Tilting-box sampler is one in which the tilting box is both the timer and the mechanical means for moving the cutter. Cutter travel is normally curvilinear, although rectilinear motion is readily obtained by a simple link motion (see Fig. 36). In the form shown in Fig. 33 the scoop *d* is made of a piece of sheet steel cut and bent to proper slope for discharge of the sample and riveted against a 3/4-in. wedge-shaped block to close the back; angles *g* prevent drip from sides into the sample. It is mounted on a stiff frame *a*, made of two pairs of 1 1/2 × 1 1/2-in. angles, back-to-back, carried on pivot bolts *b*, roller *c*, and plate *e*. The carriage is dragged back and forth across the stream by rod *f* attached to upright *i* of the tilting box. The upright is pivoted on a shaft *v*; it carries below the pivot a bumping frame *k* and, at the lower end, paddle *l*. Teeter box *m* is also pivoted independently on shaft *v*. This box is divided by a central transverse partition and is provided with two check valves.

Operation is as follows: With the box empty and in the position shown, constant-head water enters the upper compartment through pipe *n*. When this compartment is full enough to cause release of the spring catch *p* the box tilts freely until it strikes the upper end of bumping frame *k*, which then moves downward and swings upright *i* across into position i_2, and thus, through rod *f*, drags cutter *d* across the stream. At the end of the swing the tilting box strikes bumper *q* and pin *r* opens check valve *x*, allowing the water to run from the tilting box into the tank below. The other end of box *m* now fills, and the cycle is repeated. The level of water in the lower tank is regulated by plugs *s* at such a height that the paddle takes up the shock of the striking teeter box and causes uniform motion of the cutter. The sensitivity of the mechanism is increased by the suspended weight *t*, which raises the center of gravity of the tilting frame; this weight also aids in holding upright *i* in off position against the weight of the paddles, and, by reason of its inertia during the swing, prevents stoppage at dead center. Timing is regulated by a valve on water line *n* which should be on an open-pressure tank with float valve or constant overflow.

In other forms the cutter swings in an arc in a vertical plane on an arm depending from the tilting box or the tilting-box shaft. Motion is then akin to that of the cutter in Fig. 29.

Piston-actuated vertical-swing sampler used at ALASKA GOLD MINING Co. is shown in Fig. 34. The cutter consists of steel sheets *a* mounted on a slot in inclined pipe *b* supported by stirrups *c* and swung through a stream issuing from the bottom of box *d* by movement of the water-actuated piston *e*, controlled by a Scobey timer (Fig. 41). Reject discharges from the side of box *f*, and sample passes into *g* and through pipe *h* into sample receptacles *k*.

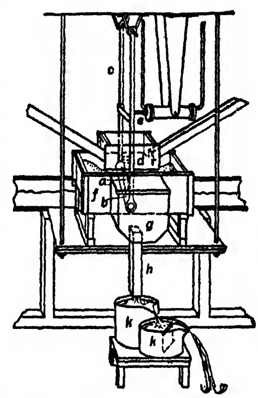

FIG. 34. Piston-actuated sampler, ALASKA GOLD MINING Co.

Straight-Path Samplers

Straight-line cutter travel is theoretically best, since it is readily arranged to give equal time in each portion of the stream, which no curved-path cutter can do without an elaborate differential movement too complicated and expensive to be practical. Drives and timers are of wide variety.

Chain-bucket sampler (Fig. 35) is representative of a type of straight-line sampler widely used for dry ore. In the form pictured (VAN MATER) it consists of a sprocket-chain sampling conveyor set under and carrying a sampling bucket through the discharge of the main conveyor. The sampling conveyor is driven by pulley and belt from the head end of the main conveyor. Any number of sampling buckets may be used according to the frequency and size of sample desired. The buckets must be at least as wide as the stream delivered by the main conveyor. The sample cut by the buckets is dumped into a sample hopper *a* as the bucket passes over the head sprockets. A wooden wearing block is fastened to the bottom of the buckets to take wear when the bucket passes through the stream of ore on the return trip. The proportion taken for a sample is the percentage of the total length of sprocket chain that is represented by the distance between the cutting edges of a bucket, multiplied by number of buckets. The bucket must be deep enough to prevent material from bounding out (*88 J 1282*).

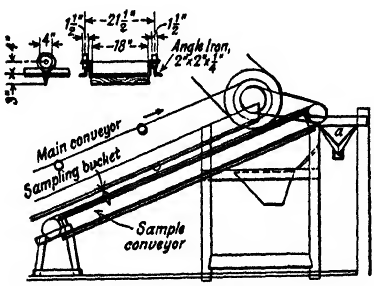

FIG. 35. Van Mater sampler.

In the more usual form of this sampler the buckets are of tilting type and the travel is at right angles to the stream (in the case of a conveyor discharge, in a horizontal line at right angles to the vertical plane of the conveyor axis), with the return run usually above the sampling run.

In the variant used at MIDVALE (*IC 6492*) a double cut is taken by the same conveyor system. The sampler consists of a double-chain tilting-bucket elevator-conveyor (Peck type, Sec. 18, Fig. 66), with 2 @ 3×9-in. buckets, arranged to cut the discharge of a belt conveyor, and dump the sample into a small hopper discharged by a horizontal-disk feeder, the stream from which is again cut by the sample buckets on the lower run. The final sample then discharges into a bin. Ratio per cut is 1 : 50, hence final sample ratio is 1 : 2,500.

Tilting-box straight-line sampler consists, in the form pictured in Fig. 36, of a wheeled carriage *a*, running on a track on the supporting frame, and carrying three dependent

scoops *b* which are actuated by arm *c* from the tilting frame *d* mounted on pivot shaft *e*. Constant-head water from pipe *f* alternately fills kegs g_1 and g_2, which are emptied in down position when spring-plugs *h* strike their respective bumping blocks. Carriage travel is not uniform, owing to acceleration of the tilting frame and variation in the effective length of arm *c* during the stroke.

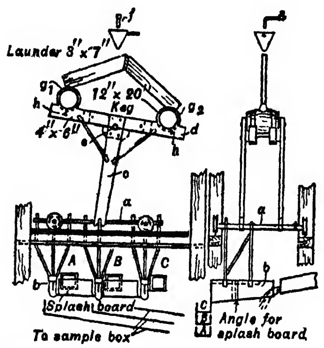

FIG. 36. Tilting-box sampler with three scoops.

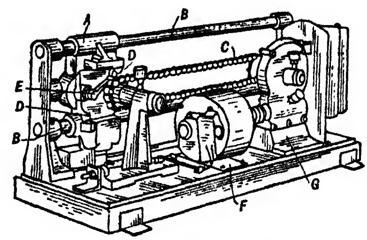

FIG. 37. Geco sample-cutter drive.

Geco sampler (Fig. 37) is typical of a common form of drive for straight-line cutters, applicable both to dry- and wet-pulp sampling. It consists of a suitable sample cutter mounted on carrier *A* and driven back and forth horizontally on rods *B* by an extending roller pin on roller chain *C*, which engages lugs *D* on *A* through linkage *E*. Chain is driven by motor *F* through reducer *G*. When the limits of carriage travel are reached, power is cut off by a limit switch, and is restored, after some desired interval, by a time switch operated by a Telechron motor (Fig. 42). Standard sampling intervals are 5, 7.5, 10, 15, and 30 min. Cutter travel, determined by the distance between sprocket centers, is 16 to 20 in. in the standard machine. Greater distances are available in larger sizes.

Geary-Jennings sampler has the cutter carriage actuated by a heavy motor-driven screw, the general arrangement being otherwise similar to Fig. 37. Drive is from a reversible, synchronous motor. Limit and time switches control length of stroke and cutting interval. Stock samplers travel at a constant rate of 5.7 in. per sec., with stroke lengths of 15 to 60 in. Sampling interval is adjustable.

ADVANTAGES. These samplers take a cut of the stream as represented graphically by Fig. 22, item *B*. This is correct sampling, especially since the frequency of cuts may be varied by the operator to suit the individual sampling problem. Any disadvantages which exist accrue from the method employed to drive the cutter. This should be positive and capable of producing uniform motion across the stream. The delicate electrical equipment is, perhaps, a disadvantage, since it requires expert attention. Ordinarily, maintenance consists of resurfacing contact points or the like.

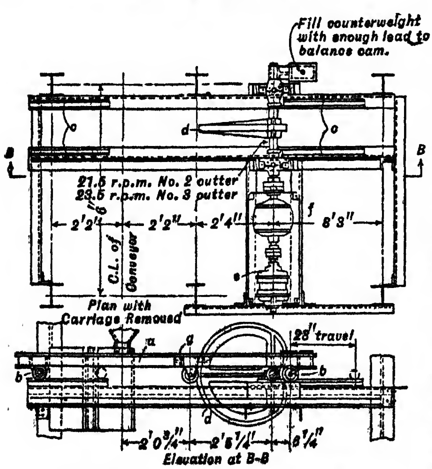

FIG. 38. Cam-driven cutter carriage.

Cam-driven cutter carriage (Fig. 38) was developed at UTAH ORE SAMPLING CO. (*129 J 223*). Carriage *a*, supported on wheels *b*, is mounted on two short parallel tracks at the ends of the frame. It is actuated by cam *d*, driven at constant speed by motor *e* through reducer *f*. Cutters have sharpened lips of manganese steel. The stream is cut alternately from each side. The cam must be designed properly to produce uniform motion of the cutters through the stream, and it must fit snugly between the idling rollers on the carriage to eliminate backlash and jerking. Take-up *g* on the front idler permits necessary adjustment. Spacing of the cutter walls determines the percentage of material taken for sample, a 6-in. width is used to sample $^3/_8$-in. material and a 3-in. width for $^3/_{16}$-in. and 10-m. material. Frequency of cut is determined by the r.p.m. of the cam. Travel is 23 in.

At UTAH COPPER CO. straight-line cutter carriages on tracks are driven by individual motor-reducer units actuated from a central control timer. The reducer drive shaft carries a pinion which drives a guided rack, attached by a rod to the cutter carriage. (See Fig. 43, item *B*.)

Arrangement of straight-line cutters. Several arrangements are shown in Fig. 39. *A* and *B* are typical for fine wet pulps, the sample being delivered by pipe through a slot in the side of the junction box. *C* and *D* show arrangements for cutting streams of coarser material delivered by conveyor and vertical chute respectively. The carrier arm

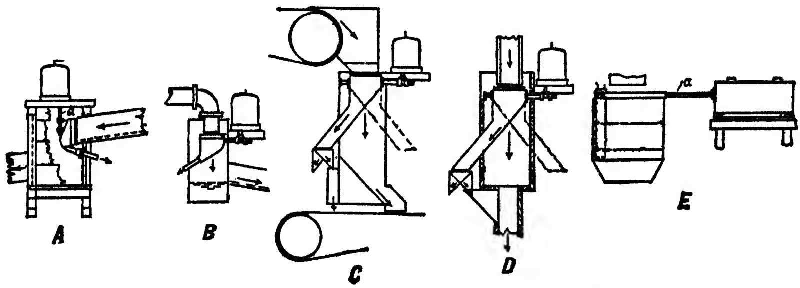

FIG. 39. Arrangements of straight-line sample cutters (*after General Engineering Co.*).

a may, if desired, be extended in the line of travel, as shown in *E;* this is a better arrangement for heavy cutters, which may then be mounted on a yoke-drawn wheel carriage as depicted.

Co., Inc., Mine and Smelter Supply Co., Morse Bros. Machy. Co., Southwestern Engineering Co., Stephens-Adamson Mfg. Co., Traylor Engineering and Mfg. Co.

Timers

Timing traces back in all cases to a controlled rate of flow of a fluid, with some form of mechanical reaction to mark the end of the desired interval. Classification of timers is on the basis of the means of marking the interval and of transmitting the impulses then occurring. (*a*) TILTING-BOX (Figs. 33, 36) is the simplest and most direct form. (*b*) MECHANICAL TIMER depends upon interruptions in the impulse of a revolving shaft held to a constant speed by a governor on the driving engine. (*c*) ELECTRICAL TIMER is a variant of (*b*) in which the immediate constant-speed shaft is that of a synchronous motor.

Tilting-box external timer is shown in one form in Fig. 40, in which the box in swinging actuates a two-way pressure-water valve that admits water alternately to the two sides of a piston in a long cylinder, the piston rod actuating the cutter carriage.

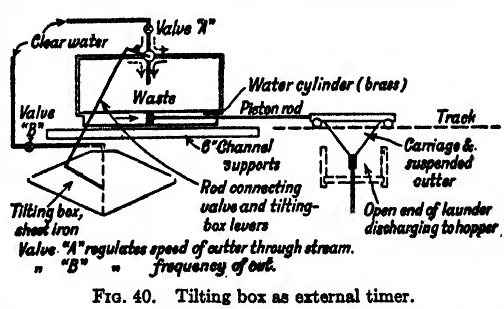

FIG. 40. Tilting box as external timer.

Tilting boxes are subject to variations in water supply, as respects both flow rate and density. If, however, fresh water is used, drawn from a tank in which constant head is maintained by continuous overflow, with an alarm for failure; and the flow to the tilting box is of reasonable volume so that the flow-controlling means is not of too small aperture, the device is sufficiently accurate for all normal sampling operations in ore-dressing plants.

Scobey timer (Fig. 41) is of the interrupted-gear type. It is used to operate samplers directly or to control the power for the actuating mechanism. It is driven by belt from a convenient source of power at about 20 r.p.m. Motion is transmitted through bevel gears *a* to a chain of intermittent gears which move a sliding frame *b* from side to side. A lug *c* on the sliding frame causes arm *d*, pivoted at *e*, to swing back and forth. The cutter *f* is attached directly to the swinging arm, or the arm is connected to a switch or valve controlling the power operating the samplers. The position of the pivot of the swinging arm may be varied by turning handwheel *g*, thus changing the length of this arm of the lever and consequently the speed at which the cutter moves. The arc which the arm describes may thus be varied from 10 to 22 in. in length. By using different

combinations of intermittent gears, the intervals at which a stroke is made can be varied from 1 min. 20 sec. to 5 min. 20 sec., when the driving pulley is making 20 r.p.m. With a 2-in. cutter attached to the swinging arm and by varying adjustments as above, samples from 1/1,000th to 1/11,000th part can be obtained. When arranged as shown and taking the discharge from a launder, only 10-in. fall is required.

Various other mechanical timers are on the market.

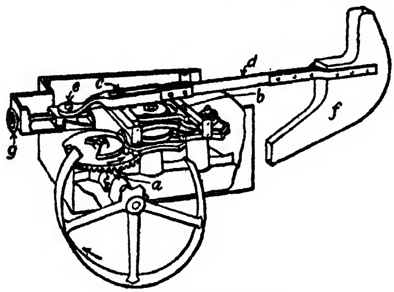

FIG. 41. Scobey timer.

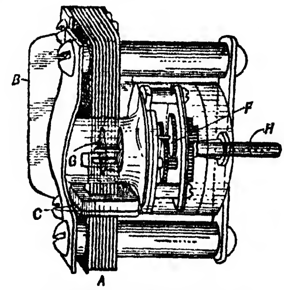

FIG. 42. Telechron motor.

Synchronous-motor timers are of the self-starting clock type which operate in synchronism with an a.-c. frequency. When operated at the rated load they attain synchronous speed, starting from rest, in a fraction of a second. Speed is independent of drops in line voltage providing these do not exceed 20%; it is also independent of temperature changes ranging from 0° to 100° F., but for temperatures outside this range a special lubricant must be used.

Telechron motor is shown in Fig. 42. Bipolar field A is excited by a coil B drawing power from a single-phase a.-c. circuit. The shaft H of the motor carries at one end a set of rotor rings G, made of thin, hardened, magnetic steel, which fit in slots cut in the pole pieces. They are caused to rotate by producing in the magnetic field a tendency toward rotation. This is done by placing copper shading coils C upon one of the arms of the magnet, which cause the flux in this arm to lag behind the flux in the unshaded arm. This field acting on the remanent magnetic poles of the rotor rings causes the shaft to rotate. A gear train F is used to reduce the speed of the output shaft of the unit.

Both light-duty motors and motors for light power and comparatively heavy duty uses are available. Accuracy is to a fraction of a second, if the line generator speed is constant.

Central timing systems and controller units are used to eliminate duplication of equipment, provide for remote control by one operator, and prevent access of unauthorized individuals to the sampling system. Housing of individual samplers and sample containers is common practice.

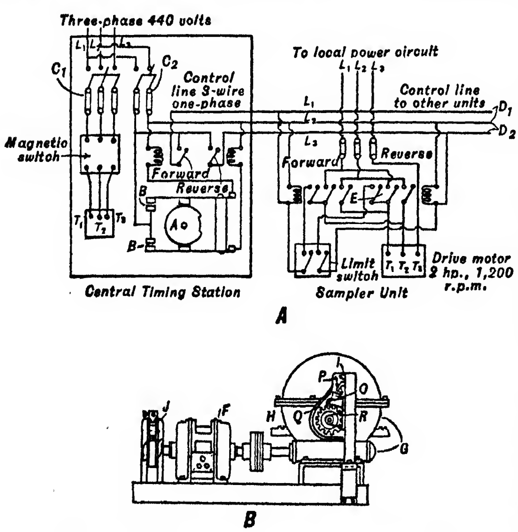

FIG. 43. Timing system ar UTAH COPPER CO.

At UTAH COPPER CO. a central timing station (Fig. 43) is used to control a system of automatic electric pulp samplers (*130 J 556*). The timer disk A is driven at 20 m.p.r. by a $1/8$-hp. induction motor through an enclosed gear train of high reduction, giving a 10-min. time interval between the upper and lower contacts B. Two single-pole magnetic switches C_1 and C_2 are thus energized alternately, and alternately energize the sides of the 3-wire control line D_1 and D_2. These currents control the individual reversing switches E of each sampler unit only; they do not power the driving mechanisms of the sampler units. As the reversing switch of the sampler unit closes, its own holding circuit functions to make the switch independent of the control current, so that only momentary contact at the timer is needed.

The drive unit of each sample cutter consists of a 2-hp. induction motor *F*, enclosed worm reduction gear *G*, rack *H* attached to the cutter car, a limit switch *I*, and a magnetic brake *J*. The limit switch is coupled directly to the worm-wheel shaft. Cam *O*, which actuates the levered carbon contact *P*, is rotated at its proper speed by means of a pinion *Q* on the cam shaft and a gear *R* of proper ratio. When the cutter completes the stroke, limit switch *I* opens the circuit of the reversing magnetic switch, the motor stops, and the magnetic brake prevents further movement of the cutter. At the end of 10 min. the cycle is repeated but in the opposite direction. The length of the stroke of the cutter is controlled by the limit switch, so that streams of different width may be sampled. The reduction ratio of each sampler unit controls the sampling time. The central timing station controls only the frequency of the cuts.

At the Bird Dog Mill (*131 J 351*) a central controller unit with compressed-air transmission is used to control the automatic samplers and the flow of ore in the primary crushing section. The mill treats ore from three different mining tracts, hence tonnage and head assay of each ore must be determined accurately. Tonnage of incoming ore is determined by a track scale. Ore from each tract is stored in a separate bin. Each ore is crushed separately by a jaw crusher; a 10% sample of this product is delivered to the corresponding separate sample bin. These samples are subsequently crushed further and sampled in steps (see Fig. 65). The discharge gate of each coarse-ore bin is actuated by an air-driven piston. The actuating cylinder of the samplers (Fig. 44, item *A*) consists of two opposing pistons *a* attached to a common spindle *b* carrying a gear rack which meshes with a gear segment *c* onto a pinion shaft *d* to which the cutter is fastened. Periodic diversion of compressed air from one cylinder to the other swings the cutter across the stream. The interval between swings is controlled by a master poppet valve driven by chain and sprocket from the main line shaft of the mill (see item *B*).

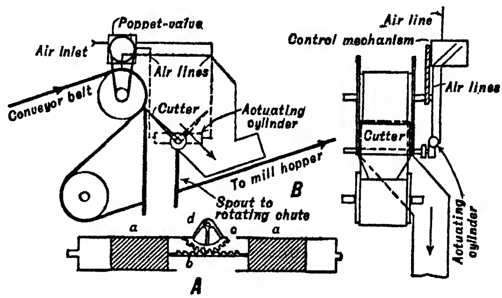

Fig. 44. Arrangement of head sampler at Bird Dog mill.

The rotating feed chute of the sample bins is turned to the proper bin by means of a pinion keyed to its shaft and engaged by a rack. Movement can be imparted to the rack by any one of four actuating cylinders, each of which moves the rack through a different distance.

The central controller unit consists of four air valves, each of which has a two-way discharge, one connected to the bottom side of the actuating cylinder of one of the coarse-ore bins and the other to one of the four cylinders controlling the rotating chute so that the chute is moved into the feed position of the corresponding sample bin. Simultaneously with this performance air enters the top of the actuating cylinders of the other bins and closes the gates. A locking device actuated by an auxiliary air cylinder inside the controller panel locks the controller mechanism so that none of the other hopper gates can be opened, and sets a time lock that introduces an interval between the closing of one gate and the opening of another, thus allowing time for discharge of material on conveyors. The gates and rotating chute are equipped with commutators so situated that a signal light goes on at the controller panel when the corresponding unit is in operative condition. The controller air valves are operated by levers equipped with a gravity catch in the operating position. The locking mechanism noted above prevents movement of all levers save the one in the operating position.

At Empire Zinc Co., Gilman, Colo. (*132 J 480*), a combined mechanical and electrical limit switch and timer (Fig. 45) operates the samplers. A common timer shaft *A* carries a set of cams, one for

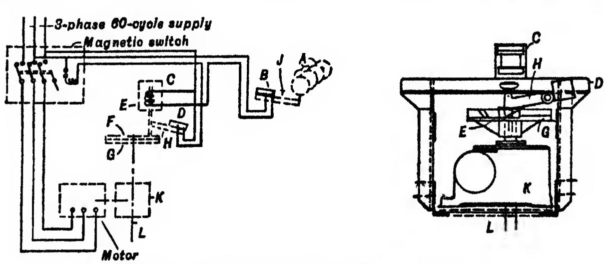

Fig. 45. Timing mechanism at Empire Zinc Co.

each sampler. The cams tilt rocker arms *J*, which close individual mercury switches *B* controlling current to solenoid *C*. The energized solenoid lifts a roller *E* out of a slot *F* in a circular track on table *G* and simultaneously tilts the rocker arm *H*, which closes mercury switch *D*; this starts a 1/4-hp. motor which drives the sampler through speed reducer *K* and sampler shaft *L*. As soon as movement of the table begins, switch *B* is opened by rotation of cam *A*. The solenoid is thus de-energized and the idler drops onto the circular track. Movement of the table continues until the slot in the track comes

under roller *E*, when the roller drops into the slot and allows the solenoid plunger to drop and open switch *D*. Thus a complete revolution of the cutter is obtained. A rotary sampler traveling at 8 r.p.m. on shaft *L* and taking one cut every 2 min. will give a sampling ratio of 1 : 24, 130 for a 1/16-in. cutter width and 30-in. average diameter of cutter circle.

Checking Automatic Samplers

Recording devices. It is essential to accurate sampling to install a recording device on automatic samplers in order to have a check on performance. The simplest recorder is a revolution counter, set to count each cut; the counter is read at beginning and end of the sample period giving the number of cuts and therefrom the average sampling interval. This device does no more, however, than point a lack of cuts in case a sampler is stuck for a part of the sampling period; it tells nothing as to when the hang-up occurred, nor as to whether it occurred in mid-stream. Too few cuts indicates unreliability of the sample; too many may point to unreliability of the counter.

Graphical recorders of the Bristol or similar type, arranged to indicate the length of travel of the sample scoop at each cut and the time of the cut, give all information necessary as to performance, in the shape of a chart presenting graphically the relation between time and scoop travel. If the chart indicates that the scoop has stuck in mid-stream, the sample should, of course, be discarded.

Calibration of samplers is illustrated by practice at Empire Zinc Co. (*132 J 480*). A 50-gal. barrel equipped with valve and hose outlet is filled with saturated sodium chloride solution, which is run at a uniform rate into the stream ahead of the sampler for 5 to 20 min., time being determined with a stop watch. During this time sampler cuts are collected separately. These samples and blank solution samples are assayed for Cl^-. From the assays, volume of salt solution added, and pulp density of the samples, the sampler ratio is computed.

4. TONNAGE AND MOISTURE DETERMINATION

Determinations of weight of ore delivered to or passing through different sections of a mill are necessary in order to keep close check on operations. Where ore is being accepted at a mill from a seller, the weight must be determined as accurately as possible; in plants that are milling company ore, the weight need be determined only approximately, as a rough check on working. Many schemes are used for tonnage determination, some are accurate and some mere approximations that depend on averages over long periods of time for dependable results.

Track scales are used for carload lots. They ordinarily require the services of an operator who balances the load on the scale beam and notes the weight on a suitable form. This method gives correct results within a small error (0.5%) but has the disadvantage of relying on the care and accuracy with which the operator balances the load and notes results. With recording scales the operator merely balances the load, then turns a screw which automatically punches a card and records the weight. Some track scales weigh a train of ore automatically as it passes slowly over the platform. This does away with the personal factor entirely except for occasional standardization. The car must stand free and completely on the scale; snow and ice should be removed before weighing.

Platform scales are used like track scales when wagons or trucks deliver the ore. The tare must be accurately determined. Unless the scales are in perfect adjustment, the load should be centered as nearly as possible at both loaded and empty weighings, or should stand at the same place for both weighings. Naturally, helpers or guests of the driver who weigh in on the full load should accompany the empty wagon over the scales. The wagon should be at rest when weighed and, in case of animal-drawn vehicles, traces should hang loose.

Automatic dump scales consist of a hopper which receives ore until full, when the weight is recorded and the material run out automatically. This is accurate. Considerable space is required, however, and operation is intermittent, making it necessary to use two units where a continuous stream of material is wanted, so that one will be discharging while the other is filling. Care should be taken to insure that all material runs out before new material is run in. (See also Sec. 3 A, Art. 6.)

Conveying weighers are attached to conveyors and automatically record the weight of material being carried. They occupy but little space and need no attendance except for occasional standardizing and adjustment. They are accurate to within 0.5% when kept in proper adjustment. Several different types may be obtained. (See also Sec. 18, Art. 23.)

Blake-Denison weigher (Fig. 46) suspends a short section of conveyor from the short arm of steelyard a, which is balanced to the weight of the unloaded conveyor. The load on the conveyor is balanced by a plunger b suspended in a mercury dashpot c. Shaft d, driven through bevel gears from a pulley revolved by the conveyor, is fitted with cams so that every time the conveyor travels through the suspended distance these cams operate a device e, which grips the steelyard, and a measuring quadrant f that rotates the ratchet registering wheel g a distance depending on the position of the steelyard. This amount is recorded on indicator h, calibrated for the units desired. The machine needs no attendance except occasional inspection and calibration with known weights.

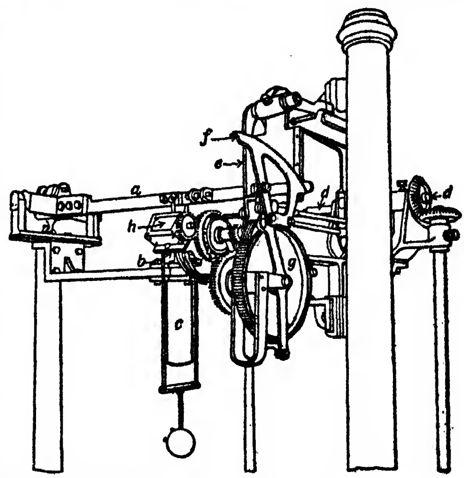

FIG. 46. Weighing and recording mechanism of Blake-Denison automatic weigher.

Checking operation of the weigher is usually done by feeding known weights of ore to the conveyor at a regular rate for a given period of time. At one plant (*100 J 520*), if the automatic weigher checks within 50 lb. in 8,000 lb. in comparison with hand-weighed feed, it is considered accurate enough; if a larger discrepancy is recorded, the weigher is adjusted. To insure proper operation, checking should be done at frequent and regular intervals.

Merrick Weightometer (Fig. 47) is so arranged that, instead of weighing the load on the conveyor by a succession of weights of short sections, the weight is taken continuously by means of a specially designed integrator. A portion of the conveyor is suspended by means of rods a from weighing levers l that operate beam b. The weight of the load at any instant is automatically counterbalanced by an iron float c attached to the beam. This float is partly immersed in a bath of mercury and thus as it rises or falls its gain or loss in buoyancy compensates for variations in load. The extreme end of the beam is connected by rod d to a totalizing mechanical integrator. The integrator (Fig. 48) consists of an aluminum disk X which has rollers Y around the periphery, the axes tangential to the edge of the disk and free to revolve. The disk is attached to shaft s which revolves in bearings on frame Z. The frame is mounted on bearings at both ends, which permits it to rotate on an axis that lies in the plane of the disk and passes through the center thereof. A link at one end of the disk frame is attached to rod h (d, Fig. 47) so that any movement of the beam causes the frame to tilt through an angle whose sine is proportional to the vertical movement of the float which, in turn, is proportional to the load on the suspended portion of the conveyor. Four pulleys (U, U, Q, Q) drive an endless belt W, which touches rollers Y at two points diametrically opposite on the axis of the frame Z. Contact between the disk rollers and the belt is maintained by pressure rollers behind the belt. The take-up pulley T is weighted and insures an even tension of the belt and takes care of any stretch.

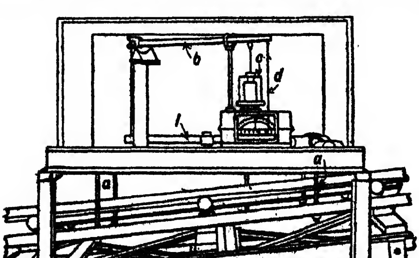

FIG. 47. Merrick Weightometer.

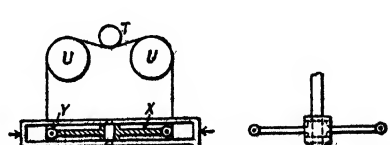

FIG. 48. Merrick integrator.

The two pulleys U are geared together and driven by means of gears from a bend pulley under the return conveyor belt, or from a sprocket, if link belt is used. When the belt is running unloaded, the machine is adjusted by means of an adjusting weight on a screw attached to the beam so that the disk remains vertical. In this position motion of W causes rotation of rollers Y but no rotation of the disk. When a load comes on the conveyor, motion of the beam causes the disk frame to tilt, the axes of rollers Y become inclined to belt W, and the belt pushes the rollers sidewise, causing the disk to rotate at a speed proportional to its inclination, *i.e.*, to the load on the conveyor. Revolution of the disk is recorded on a counter calibrated to read weight in the units for which the machine is designed. Thus the two factors, speed of belt and weight carried per unit of length, are accounted for.

This device can be used for weighing material transported on belt and bucket conveyors, cable railways and overhead transporters. A special attachment can be procured that counterbalances a varying empty weight of conveyor, should the material handled adhere to the belt on the return trip.

Toledo Chronofio is similar in principle to the Merrick; it determines belt loading continuously and utilizes an integrator to combine this determination with a belt-speed determination to give total weight. By balancing the return belt against the loaded belt, compensation may be made for material clinging to the belt and the integrator then gives net weight.

Electric weigher operates on the principle that the amount of current flowing through an electric circuit is proportional to the product of the voltage and conductivity of the circuit. Voltage proportional to the speed of the conveyor is produced by driving a constant-field dynamo by gears or a chain and sprocket attached to the driving shaft of the conveyor. Conductivity is varied with change of load by a rheostat operated by a plunger in a mercury dashpot. An ampere-hour meter in circuit is graduated to read in units of weight. A section of the conveyor is suspended in a manner similar to that employed in the Merrick Weightometer. A counterweight on the scale beam balances the empty weight of the conveyor while the weight on the beam due to the load carried is counterbalanced by motion of the plunger in the dashpot. To provide for varying weight of the empty belt, a corresponding length of the unloaded part of the conveyor is suspended so that it operates on the opposite side of the scale beam from the loaded portion. The machine is calibrated by moving riders astride two wires of a loop of the rheostat when standard weights are suspended from the scale and the dynamo is run at a known speed. Instruments may be attached to the system to record the rate of handling, time of starting and stopping, and continuity of operation; these instruments may be placed at any desired distance from the weigher. By connection of the scale with a device controlling the feeder, delivery of material at a certain rate or delivery of a certain predetermined amount may be effected.

Approximate methods of weighing are used when great accuracy is unnecessary or investment for a scale is not warranted. Carloads or trainloads are counted and the weight calculated from the volume of the cars and the weight of a unit volume of broken ore. In some cases carloads or trainloads are weighed occasionally and this weight used as a basis for calculating total tonnage from the number of cars or trainloads counted. Bin measurements of volume are frequently used as a rough check on other methods, or in company mills for inventory at the end of statement periods. Tonnage may be estimated by counting the number of strokes or revolutions of feeding devices, the weight of ore fed at each stroke or revolution being determined experimentally.

At the PORTLAND mill (*63 A 514*) the weight of ore passing was determined as follows: Once each day one Chilean mill was stopped and the feed discharged into a box for 20 strokes of the feeder plunger. This sample was weighed and the average of the five latest weights, applied as factor to the number of strokes of the feeder plunger as indicated by a counter, gave the tonnage per 24 hr. A similar method was used at the ROSEBERY concentrator. (*114 J 677.*) Ore at 1-in. size was sampled every 15 min. by catching the full discharge of the feeder for a period of 30 sec.; alternate-interval samples were weighed.

Wet-pulp tonnage is ordinarily computed from volume measurements and moisture determinations. The usual problem is that of finely ground material suspended in water and flowing in pipes or launders. The whole stream is deflected into a suitable container during a period of time measured by a stop watch. Volume is determined by graduations on the container or by measurement. The proportion of solids is determined from a small dip sample taken while the container is filling. If the stream is small, the whole amount diverted may be used to determine the amount of solids in the pulp. Percentage of solids may be determined either (*a*) by weighing, dewatering, drying, and weighing the dry solids; or (*b*) by calculation from the specific gravity of wet pulp and a value for the specific gravity of the dry material. The first method is the more accurate but takes longer; the specific gravity of the ore varies from time to time with corresponding effect on computation. Sometimes a cutter of known width is used to catch a time sample and the weight is multiplied by the ratio between width of stream and width of cutter to determine the amount carried by the whole stream. This method is not so accurate as the first because the stream varies in depth and density across its width. Results by this method will be most satisfactory when the material is very finely ground. Tonnage of ore in an agitating tank whose volume is known may be calculated from a dipper sample; the accuracy depends on the degree of pulp uniformity caused by the agitation. The volume of pulp passing through pipes is sometimes measured by solution meters and tonnage calculated from small specific-gravity samples.

Orifice control of flowing pulp by the periodic opening and closing of a collapsible rubber tubing which terminates an oversize orifice is recently reported by U.S.B.M. (*RI 3750*). This device, known as the PERIODIC PINCER, has been used to control pulp flow ranging from 50 lb. to 4 t.p.h. of solids.

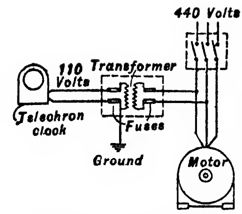

FIG. 49. Pump timer.

Calculations and pulp formulas, see Art. 24.

Timing of solution-tonnage determinations was done at HOMESTAKE (*132 #7 J 306*) as shown in Fig. 49. The branch line tapped off the 440-v. pump line was stepped down to 110-v. and then operated a Telechron clock, which thus worked only when the pump worked.

Percolation rates may be determined by means of the homemade device shown in Fig. 50 (*132 #7 J 306*).

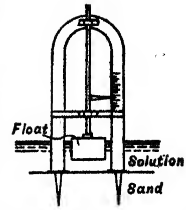

FIG. 50. Percolation indicator.

Moisture Sampling

Moisture samples are necessary to determine net dry weight from gross weights obtained by any method. The same care should be used in taking them as in other sampling. They should be weighed immediately or be held as briefly as possible in tight containers that prevent evaporation. Calculation is simplified by taking samples weighing 100 gm. or 1,000 gm. or small multiples of these weights. Samples are weighed wet, dried at a suitable temperature until all hygroscopic moisture is driven off, then weighed again; the difference represents moisture and is usually expressed as percentage of the wet weight.

Moisture samples should be taken at the time the bulk material is weighed, if possible, to avoid errors due to evaporation or subsequent wetting, hence they are generally taken at different times than assay samples. Some form of grab sampling is frequently used so that the sample can be quickly collected and placed in tight containers. The assumption is that error due to crudeness of method is less than the error introduced by longer exposure of material during more elaborate sampling. Grab samples for moisture are frequently taken from the end of a conveyor belt after material has passed over a conveying weigher.

It is difficult to obtain duplicate moisture samples that check within close limits. When ore is shipped in cars, the outer or top layers contain more or less moisture than the bulk, depending on climatic conditions; if shipped in bags, the material will probably be drier near the outside of the bag than in the middle. Thorough mixing must precede an accurate sample. If the regular sample mill is used for a moisture sample, drying in passage through the sampling mill is considerable and must be compensated in the calculation. This is usually done by an arbitrary percentage added to the percentage determined. Brunton (*40 A 567*) says that, in ordinary practice, this loss would not exceed 10% of the percentage determined in summer, nor 7% in winter. In buying and selling, a factor is determined by agreement between the parties; in one instance 10% of the percentage determined was added with a maximum addition of 1% of water based on the wet weight (*TP 86 USBM*). Duplicate determinations on relatively dry material (say under 10% moisture) should check within 10% of the percentage present.

Tests by the U. S. Bur. of Mines of 254 pairs of duplicate moisture samples of coal showed an average difference in moisture content of 0.256% with a maximum difference of 3.6% (*Bul 116 USBM*). The method employed was to use the same 15-lb. sample, obtained as described on p. 29, for determination of moisture and for analysis; it was kept in sealed airtight containers until the moisture determination.

Moisture-box used for iron ores is made with a burlap bottom overlain by 1/8-in. wire-mesh screen. The wet sample is placed in the box and allowed to drain for 24 hr., protected from the weather. The method is slow, and requires application of a factor that will vary to an unknown degree with size and mineralogical character of the material.

Car drainage method, sometimes used for iron ores, consists in applying a predetermined car drainage-rate factor to weights determined at either shipping or delivery point. Considering the inconstancy of the weather and railroad manipulation, it can have no even colorable pretense to accuracy.

5. MILL SAMPLING

Samples of feed, tailing, and concentrate or other valuable product are taken in all well-run mills to cover operating intervals short enough to permit effective control of operation. In general this period is the shift, but with a variable feed, or with a process not susceptible of ready and accurate control by visual indications, sample periods may be as short as 30 min. These samples are taken on definite schedules, either automatically (Art. 3) or by hand methods (Art. 2). The interval between cuts varies according to the material sampled (Art. 1); it is usually longest for tailing, and least for concentrate.

Head Sampling

Practice varies according to the ore, the method of treatment, and the capacity of the mill (see Table 22).

Head sampling of gold ores in general, and of spotty ores in particular, is an expensive and difficult procedure. In some cases no head samples are taken (WRIGHT-HARGREAVES), gold content of heads being estimated from bullion, tailing sample, and feed tonnage. At KIRKLAND LAKE a hand sample of ball-mill discharge and of the entering storage solution is taken every 2 hr.; density is determined; composited 24-hr. samples are divided to yield a sample which when filtered and washed gives a combined filtrate of about 600 cc.; filtrate and solids as well as the storage-solution sample are assayed; the gold value of the plant heads is the undissolved gold in ball-mill discharge plus dissolved gold therein, minus gold entering the ball-mill in grinding solution per ton of ore, all times the daily tonnage.

If the method of treatment does not involve concentration at relatively coarse sizes, head sampling is best postponed until the sample can be taken from tumbling-mill feed or classifier overflow; by this time the ore is more or less fine and well mixed, and simple automatic samplers can be used. When the flow comprises a number of parallel or different circuits, samples are usually taken before the point of division; with parallel circuits samples may be taken after division if some tonnage determining device exists in the circuit. When sampling must be practiced at coarse sizes, a separate sampling mill is used; it usually follows the coarse-crushing plant and delivers reject to the fine-ore bins.

Mills of large capacity invariably make provision for careful sampling of heads, using automatic samplers taking frequent cuts. Hand sampling of heads is most often practiced by the smaller mills and may vary in form from grab sampling of mine cars to grab sampling of crusher product. When hand sampling is used cut intervals are normally long.

Accurate head samples are not, in general, obtained unless automatic cuts are taken at frequent intervals. Information obtained by crude methods is used as a rough check on operations. Such results, averaged over a long period, may check reasonably with results obtained by calculation from accurate tailing samples and concentrate or bullion. The extent to which head assays check calculated head assays based on product assays depends not only on the assay sampling but also on the tonnage determinations. As an aid in checking, composited daily and monthly samples are prepared from the shift and daily samples.

Tailing Sampling

Automatic wet-pulp samplers are best. Ordinarily the final tailing from a mill is low-grade, finely crushed and well mixed, and there are no sudden changes in value; hence small cuts and long sample intervals are permissible. Hand sampling is more likely to be accurate than in sampling heads or concentrate. Daily samples should be composited on a tonnage basis over a monthly period; assay of this composite should check reasonably with the average daily assay. Practice is summarized in Table 22.

Concentrate Sampling

Good practice requires use of automatic samplers with short sampling intervals. The same forms of cutters as used for sampling tailing are suitable. However, if the concentrate discharged by a machine is thick and flows sluggishly, when water is added to wash it down launders it surges so much that at one instant concentrate and the next almost clear water is flowing. In such cases automatic samplers are not satisfactory and a hand cutter must be used at the discharge of the machine or some method of sampling concentrate in bins or cars after draining must be employed. Hand cutters are used extensively. Pipe or gun samples and augers are used for sampling in bins or cars. Compositing of shift samples and of daily samples aids in checking. Sampling of concentrate in the mill is a check on the sampling at the smelter, but where considerable storage time intervenes, as in large thickeners, correspondence is to be expected only over considerable periods. Table 22 gives a summary of practice at a number of mills.

Concentrate tonnage is normally determined by weighing out on track scales, with a rough check, where possible, by bin measurement. Moisture samples are taken by hand during loading, either from the car, or, where possible, from the discharge of the loading conveyor; or are grab-sampled from the top, or pipe-sampled from loaded cars. They are useful only for rough checks on subsequent smelter moisture samples because of inevitable changes during shipment.

az 90-lb. shift sample.

Miscellaneous Mill Sampling

Miscellaneous mill samples are taken to give information concerning the operation of a particular machine or set of machines. When accurate results are desired and the sample must be taken every shift, automatic samplers are best. This is the case when a mill is operated in sections and the feed and products of each section are sampled to check its work. Ordinarily intermediate samples are taken by hand by various operators to serve as guides to operations of particular machines. Great accuracy is unnecessary, and the use of hand cutters and long sample intervals are justified.

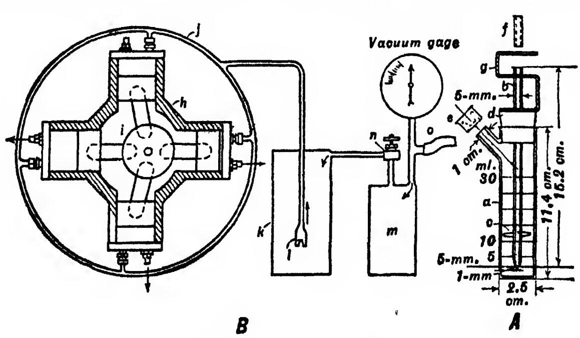
Dust sampling is done to determine the nature and number of particles suspended in the air. Dust samplers function by removing particles from the original dispersion medium under the action of an artificially applied force or forces, the dust being collected as a single-layer deposit suitable for microscopic counting (jet, Konimeter, and Electrotator), or as an unordered, multilayered deposit (electric and thermal precipitators, paper thimble, salicylic acid filter), or as a suspension in a fluid (Impinger). The jet, Konimeter, and Electrotator are necessarily limited to grab samples, since volume of air sampled is relatively small; the precipitators, thimble, filter, and impinger may be used to sample larger volumes of air. Single-layer dust deposits are quantified by microscopic counting only, since amount of dust collected is too small for accurate gravimetric or chemical quantification; counts are doubtful, since comminution or agglomeration may occur. Other deposits yield a sample sufficient for gravimetric or chemical quantification, petrological examination, and chemical identification. Table 23 summarizes characteristics of various samplers.

Table 23. Characteristics of dust samplers

Sampler	Collection, method	Industrial dust collected, %	Application *c*	Quantification, method *a*	Skill required		Sample, vol.	Power required
					Sampling	Quantification		
Impinger......	Washing	>98	L to H	M, G, C	Medium	High	Any *b*	Yes
Electrical......	Elec. precipitation	100	L to H	M, G, C	High	High	Any *d*	Yes *e*
Thermal.......	Thermal precipitation	100	PS, L, I	M *h*	High	High	1,200 cc. *f*	Yes *g*
Paper-thimble .	Filtration	100	L to H	G *j*	Little	Medium *k*	Any *i*	No *l*
Salicylic acid...	Filtration	100	L to H	M, G, C	Little	High	Any *m*	No *l, n*
Jet...........	Jet condensation	>99 *r*	PS *o, p*	M	Little	High	50 to 1,000 cc.	No
Konimeter....	Jet condensation	>99 *r*	*q, p*	M	Little	High	10 cc.	No
Electrotator...	Elec. precipitation	>99 *r*	*s, p*	M	Little	High	2 to 8 cc.	No

a C = chemical; G = gravimetric; M = microscopic.
b Rate of sampling, 0.1 cu. ft. per min.
c Dust concentrations handled: H = high, I = intermediate, L = low; PS = for particle-size studies.
d Rate, 10 to 50 li. per min.; large samples obtained rapidly.
e Some danger from high voltages.
f 6.5 cc. per min.
g Also water for aspirator.
h Sample cannot be weighed or analyzed chemically.
i Rate, 1 to 2 cu. ft. per min.; large samples obtained rapidly.
j Drying and weighing only required for most dusts; drying very slow.
k Samples may be kept indefinitely without deterioration chargeable to sampling technique.
l Water for aspirator.
m 100 li. per min.; weight recovered permits chemical work; entire sample recovered without contamination by fiber.
n Centrifuge required for extraction of sample.
o Range, 0 to 10,000 particles per cc.
p Light weight; simple to operate; rapid.
q For particle concentrations below 18×10^6 particles per cu. ft.; collection efficiency high in range from 0 to 2,000 particles per cc.; not practical for high concentrations.
r Grab sample only.
s For particle concentrations below 4×10^{10} particles per cu. ft.; collection efficiency high below 1 or 1.5×10^6 particles per cu. ft.

Midget impinger (Fig. 51) comprises a graduated side-arm tube *a*, with side arm connected to a vacuum source (item *B*), and a sample tube *b*, with spacers *c* to maintain substantially central location. Stopper *d* is of Neoprene, to avoid filler dust; stopper *e* is of the No-air type; cap *f* is a soft-rubber policeman; guard *g* is to exclude falling solid



B A

FIG. 51. Impinger dust sampler.

when *f* is off and the vacuum connection is broken. An all-glass unit overcoming the disadvantages due to deterioration of rubber and the accumulation of dust in the annular groove formed where the stopper contacts the flask is reported (*16 #5 IECA 346*).

To operate, fill *a* to the 10-cc. mark with the collecting liquid, connect the side tube to any source giving a vacuum of 12-in. water gage. Under these conditions, with a 1-mm. nozzle, air flow through the impinger is 0.1 cu. ft. per min. The resulting suspension may be counted directly, or may be diluted to give a proper concentration for easy microscopic counting (see Art. 9).

Item B shows a specially designed pump h consisting of four cylinders disposed radially at 90° about a single-throw crank i. Intake valves are connected to a collecting ring j in turn connected to a surge tank k through a check valve l and thence via a needle valve n through a second surge tank m and tube o to the impinger a. The pump is hand operated.

Paper-thimble dust sampler (*Bul 217 USPH*) consists of a single-thickness Whatman extraction shell A (33 × 94-mm.) containing well fluffed cotton wool, through which dust-laden air is drawn. Details of thimble and the brass capsule B which holds it in place are shown in Fig. 52. The suction side of the capsule is connected to a suitable pump; when the pump is not of positive-displacement type, a metering device for measuring air flow is used. Thimbles are dried to constant weight by preliminary drying at 90° to 95° C. for 3 to 7 days in an ordinary oven, followed by drying at 90° C. for 7 hrs. in a vacuum oven; drying at 90° to 95° C. for two days in a hot-air oven may be used as a substitute for the latter drying stage.

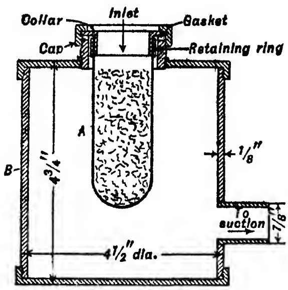


FIG. 52. Paper-thimble sampler.

Operation. Place dried, weighed thimble into retaining ring, insert collar, and screw on cap. Operate pump until desired volume of air has been filtered. Remove thimble, dry as above, and weigh.

Salicylic acid-filter sampler (*37 JCM 161, 166, 533; 38 ibid. 27*), using a filter bed of salicylic acid crystals, should be used if chemical or petrological tests on the sample are contemplated, since it yields a dry sample uncontaminated by any extraneous material introduced in collection. (A labyrinth-type collector devised to obtain 100-gm. samples for solubility tests (*38 JCM 27*) fails to collect <5-μ material effectively.)

The filter (Fig. 53) consists of a bed 3 to 4 mm. deep of <40-m. commercial-grade salicylic acid placed on stainless-steel screens A (140-m. between 2 @ 20-m.) which are in turn rigidly supported by an ebonite grid B screwed into cell C. Cell C screws onto ebonite funnel D, the joint being made airtight by a rubber gasket. The filter holder is attached by pressure tubing to an ejector-type vacuum pump E, especially designed for underground sampling where compressed air (60 lb. per sq. in.) is usually available. Capacity of the filter varies with the area and driving pressure; capacities of 7.5 to 12 li. per min. per sq. cm. of filter area are obtained using acid pads 3 to 4 mm. thick with a pressure drop of 11 to 13 cm. of Hg across the filter.

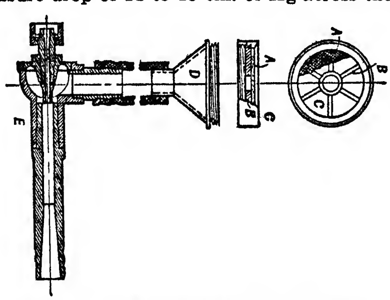

FIG. 53. Ejector with salicylic acid filter.

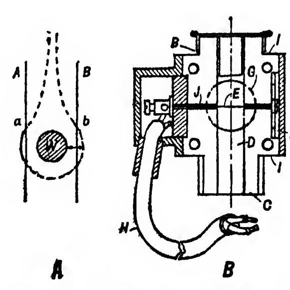

FIG. 54. Thermal precipitator (*after Watson*).

Operation. Connect ejector to air supply in sampling location. Charge cell C (this is usually done in laboratory, and a sheet of cellophane, held by rubber band, is placed around it to prevent loss during transport); level bed by shaking and smooth surface with finger (with cellophane covering still in position). Connect charged cell C to the ejector, remove cellophane and start air to ejector immediately. Read dry gas meter at beginning and end of sampling period to obtain volume of air sampled; correct by a calibration factor for the reduced pressure of the air passing through the meter. Transfer filter pad and sample to a centrifuge tube (12-cc. volume for 4-gm. pad), add 9 to 10 cc. of alcohol and separate sample from salicylic acid solution by centrifuging. Extract several times with alcohol and finally with ether to insure a dry residue.

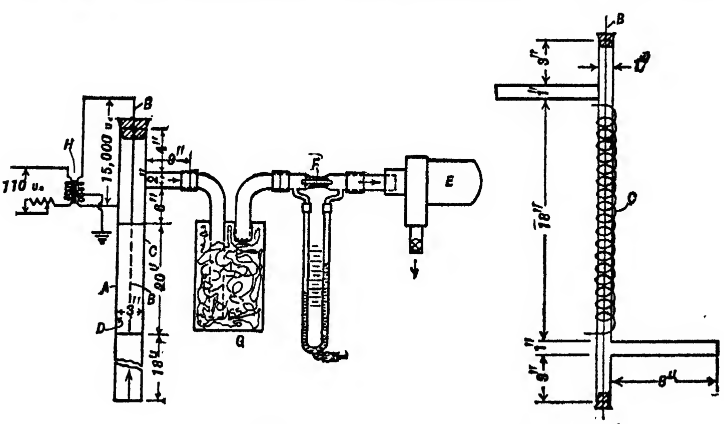
Thermal-precipitator sampler (*37 JCM 166; Medical Research Council Special Report Series, No. 199, London*) uses the dust-free space surrounding heat-radiating bodies to filter dust out of the stream being sampled. Thus if two records (cover glasses) A and B (Fig. 54, item A) are so located that the dust-free boundary (shown by dotted line) inter-

cepts the surfaces of the records and dust-laden air is drawn down slowly toward the heated wire W, particles are unable to penetrate the dust-free barrier and so deposit on the record surfaces at a and b (*32 Trans. Far. Soc. 1073*).

The precipitator head (item B) consists of two brass blocks I fastened together to form a cube with short cylinders B and C above and below respectively. Thin bakelite strips J provided with windows to leave a channel D (0.92×0.05 cm.) running vertically through the instrument (channel is a wedge widening to 0.92 cm. square at top) are clamped between the blocks and insulate a resistance wire E stretched across the center of the channel and kept taut by tongue spring F. The cover-glass records ($^3/_4$-in. circular cover glass) are introduced into the brass blocks through holes G and are held in position against bakelite strips by brass plugs pressed against them by flat springs. One terminal of the twin cable H is connected to the resistance wire, the other to the brass blocks. The cable is connected to a 2-v. battery with a fuse, ammeter, resistor, and switch connected in series. The bottom projecting cylinder C screws on to the top of a 1,200-cc. cylindrical tank, equipped with a graduated water level tube. Water leaves the cylindrical tank through an adjustable petcock (located at bottom of tank) and draws air through the precipitator head.

Operation. Clean precipitator head and wire thoroughly. (Grease on wire is removed by passing 1.2 amp. current until no deposit is evident upon clean cover glasses after a 10-min. heating period.) Place clean records in position. Fill aspirator with water to zero level. Attach precipitator head to aspirator. Switch on current and adjust to 1.2 amp.; after 10 sec. open petcock to give desired rate of flow; note time. At end of sampling period, turn off tap, switch off current, note time and volume of water run out of aspirator. Remove records for subsequent testing.

Electric precipitator (*14 J. Ind. Hyg. 364*) consists of a precipitator tube A (Fig. 55, item a) through which dust-laden air is drawn and therein subjected to an electric field



a b

FIG. 55. Electric precipitator (dimensions are in inches).

of high voltage which precipitates the dust (see Sec. 9, Art. 7) upon a lining D of celluloid or filter paper. Either of two forms of Pyrex precipitator tubes is used; the larger (in item a) is adaptable for sampling at 15,000 v. and relatively high rates of air flow, whereas lower rates and voltages are used with the small tube (item b). The precipitating or central electrode B is made of a fine wire of gold-plated drill steel in the case of the larger tube; a fine platinum, gold, or copper wire is more suitable for the smaller tube. The outer electrode C is made of either metal netting, of metal foil (as in item a), or of spirally wound copper wire (item b). The central and outer electrodes are connected to the high-voltage side of a General Electric Co. luminous-tube transformer H, operated from a 110-v. 60-cycle line; a secondary current of 30 ma. at 15,000 v. is produced. By means of a rheostat in the primary circuit, output voltages ranging from 8,000 to 15,000 may be obtained. The record may be the inner surface of the precipitator, or a snugly fitted lining of celluloid or filter paper. Air flows through the sampler under the action of a vacuum-cleaner fan E or a compressed-air ejector (Fig. 53); a flowmeter F measures rate of flow. Toxic gases which may be produced in the operation of the precipitator

are removed by a trap G containing activated charcoal. The destructive action of these gases upon rubber connections necessitates frequent inspection.

Operation. Clean the precipitator tube; insert lining (if used) and attach to air-flow system. Start fan or ejector. When flowmeter shows constant rate of flow, start current to primary of transformer and note time. Operate for desired length of time, turn off current, and remove record. Care should be taken to prevent shocks. Quantify record by microscopic counting or chemical tests.

Electrotator sampler (*18 J. Ind. Hyg. 583; 19 ibid. 579*) consists of a rotating electrostatically charged record A (Fig. 56) whose surface attracts and holds dust particles from the impinging jet or jets produced by one or more nozzles B fed by a hand-operated pump, as shown. The recording disk A, 3.2 cm. diameter, made of celluloid, is supported by table C and held by three pins D which engage three similarly disposed holes in the disk. The circular table, made of some insulating material such as ebonite, and centrally cored, screws onto the nozzlelike end of valve block E which in turn screws onto the Archimedean screw F. Screw F engages threads cut on an Archimedes spiral in plunger G and is then contained within hollow rod H. Located within the pump cylinder immediately below block E is a metal plug I equipped with egress ball-valve J. Surrounding table C is an annular flange K (ebonite), drilled on one side, as shown, to receive a small spring which bears against a small special exciter L used to assist in the electrification of the disk. An ebonite cap M is screwed down over the externally threaded flange until the rims N are in contact. When the cap is thus adjusted, the celluloid record is in sliding contact with faces O and P. Multiple-nozzle block Q fits within the cap and is located by pins. Sliding piece R is bored with holes in the same relative position as those bored through the nozzle block; it is free to rotate within the cap through an arc of 180°, the motion being controlled by a pin S passing through a semicircular cut in the cap; when properly located, it is fixed in position by a screw collar T.

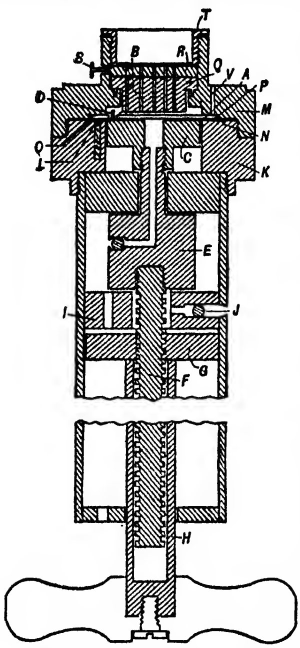


FIG. 56. Electrotator sampler.

Downward movement of plunger G causes screw F, together with the valve block E, and table C, to rotate. Disk A, which is carried by table C, is, therefore, rotated and electrified by rubbing against O and P. Downward movement of the plunger also closes valve J and opens valve E, hence air is taken into the sampler through the holes in the nozzle block. Reverse motion of the plunger closes valve E and opens valve J while table and record are caused to rotate in the opposite sense. Pump capacity is about 100 cc. per stroke; this may be varied to suit the sampling problem.

Choice of record areas is obtained by rotating R relative to Q. When R is in such position that the holes therethrough form a continuation of the holes through Q, all ingress holes are open and a maximum record area is available in the form of two or more circular tracks, depending on the number of holes through Q. When R is turned so that only the central ingress hole is open, a minimum record area, in the form of a spot, is obtained. By having several additional holes through R it is possible to select any one of the holes in Q by rotating R to the required extent, thus record areas between the maximum and minimum become available. If a track of exceptional length is required, a hole V may be drilled through the body of the cap M. The track area obtained by using an ingress hole with radius r, whose center is x units from the axis of rotation, is $4\pi xr$ square units. If, say, 5 ingress holes of equal radii were used in sampling 100 cc. of air, each hole would pass 20 cc. If the values of x for the five holes were 1, 2, 5, 7.5, and 10 mm., the record areas would increase proportionately, while the concentration of particles per unit area of record track would decrease in inverse proportion. Hence the operator may select that track which is best suited for microscopic counting.

Operation. Place a clean record in position on the table and screw down cap. Rotate slide piece until desired ingress hole (or holes) is open. Fix slide piece in position by means of screw collar T. Operate pump for the desired number of strokes. Remove record to stage of microscope and count particles in track. The number of particles N per unit volume of air is given by $4\pi rxn/V$, where n is number of particles per unit area of record and V is volume of air passing the ingress hole which made the track.

Konimeter (*Bul 217 USPH*) samples dust by impinging a high-velocity air jet formed by nozzle *A* (Fig. 57) against a glass-plate record *B*, filmed with petrolatum. Plate *B* is cemented with Canada balsam to a toothed brass ring *C* which fits snugly within the recess of brass cup *D* and is held firmly against a hard-rubber ring *E* by spring *F* attached to the inner surface of cover *G*. Brass gear *C* engages a pinion *H* operated on a rod extending outside the instrument. The face of gear *C* is circularly divided into 29 sectors, each one numbered so that a record of each sample may be kept. Two circular windows *I*, *J* cut in cover *G* permit observation of sector number and dust sample. An intake nozzle *A*, of 0.0225-in. (0 57-mm.) diameter is screwed into the base of cup *D* so that tip of nozzle is 0.0197 in. (0.5 mm.) from the prepared surface of plate *B*. The cell formed by the plate, the rubber ring *E*, and the base of cup *D* is in communication with a valveless cylindrical suction pump *K* by means of the 0.067-in. diameter hole *L*. Pump is constructed as shown in Fig. 57 and operated as in the following paragraph. Pump capacity is about 10 cc. of air per stroke; the exact amount may be determined by attaching the nozzle to a graduated gas burette containing water and noting the amount of water displaced per stroke of pump. A 5- or 2.5-cc. capacity Konimeter is manufactured by C. Zeiss (*28 JCM 79*).

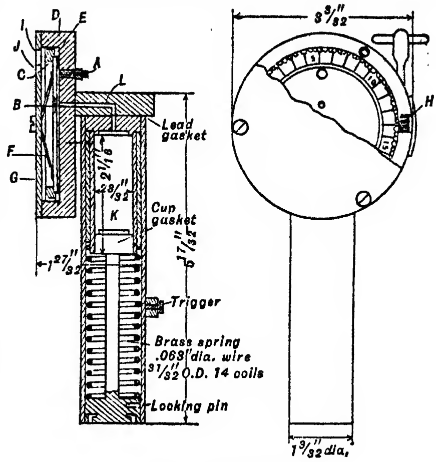

FIG. 57. Konimeter.

Operation. Clean instrument carefully; use a horsehair (or other suitable material) to clean nozzle. Clean the glass-plate record (cemented to gear) and give a thin coat of filtered petrolatum by rubbing evenly with a glass stirring rod. Assemble instrument, and turn pinion rod until sector No. 1 is opposite nozzle. Push piston inward until it is caught and held by locking pin. Locate instrument at point where sample is to be taken and press trigger. After all sectors have been exposed remove record and make a microscopic count of samples (Art. 9).

Jet collector (*4 J. Ind. Hyg. 522*) consists of a cover-glass record *A* (Fig. 58) on which impinges the dust-laden jet formed by slit *B*. A microscope cover glass *A*, 2-cm. diameter, is held firmly in the recess of ring *C* by a three-claw spring *D* fixed to the inner surface of screw-plug *E* in sleeve *F*. The joint between plug *H* and sleeve *F* is made airtight by means of a leather washer. Slit *B*, 0.1 mm. wide, is formed by two semicircular metallic plates *G* attached to plug *H* and ring *C* by countersunk screws. The cylindrical cell formed by the record, plates *G*, and ring *C* is about 1 mm. high and 2 to 10 mm. in diameter, depending on the diameter of the opening in ring *C*. An approach tube *I* is screwed to plug *H* and is lined with absorbent material (blotting paper) *J*, held in position by suitable fastenings *K* (3 or 4 coils of some brass spring wire). Sleeve *F* has an annular recess formed by the inner ends of plugs *E* and *H* which is in communication with a connection *K* for attachment to a hand air-pump of measured

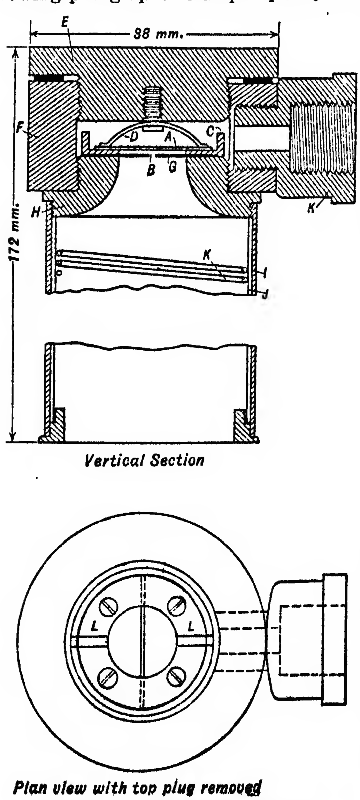

FIG. 58. Jet collector (*after Owens*).

capacity per stroke (about 50 cc.). This recess communicates with the cell through channels L cut into the upper surface of ring C. When pump is operated, pressure within the cell is reduced and air flows through the slit. The decrease in temperature of the air due to the decrease in pressure produces condensation of water vapor on the dust particles. These minute water droplets impinge on and adhere to the cover glass; subsequent evaporation of the water leaves the dust particles adhering to the record.

Operation. Moisten blotting paper in tube I with water and screw on to plug H. Attach pump and operate until approach tube I is filled with the air to be tested. Remove plug E, place carefully cleaned cover glass in position, and replace plug E (speed is essential). Operate pump until the desired volume of air is drawn through slit B, allowing sufficient time between strokes for air in approach tube to absorb water from the lining. Remove plug E and invert instrument over palm of hand to drop record out of ring. Make a microscopic count of record (see Art. 9).

Kiln-stack gas sampler (*43 #1 RP 29*) illustrates application of the principles of the filtration (paper thimble) and settlement samplers (highly inaccurate, based on settling of dust from still air on to a record) to a particular problem. Dust-laden gas, under action of pressure difference created by pump Z (Fig. 59; item a), enters nozzle A and proceeds

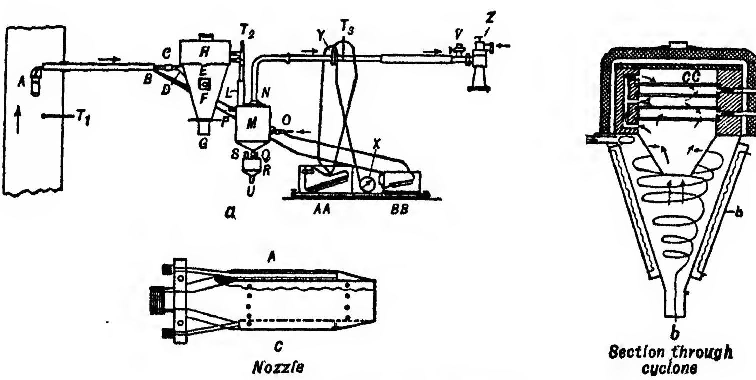

FIG. 59. Kiln-stack gas sampler.

to electrically heated (180° C.) cyclone E, where part of the dust is removed by settlement and the remainder by filtration through the paper filters CC (item b); the dust-free gas proceeding to a water separator M, where gas is cooled and water removed by condensation. Condensate is collected in a vessel R which may be drained, without interfering with gas flow through M, by closing valve Q and opening valves S and U. The cooling water enters M through O and leaves through P. The cool, dry, clean gas leaving M passes through an orifice-type flowmeter Y with differential leads to manometer AA hooked in on low- and high-pressure sides; a gage X tapped in on the pump side records suction pressures. The sampling nozzle A (item c) is equipped with static openings on the inside and outside of tube; connection to differential manometer BB shows difference in static pressures of gas flowing in stack and in nozzle. Valve V is used to control air flow so that difference in static pressures is zero. Location of nozzle within stack is such that there exists at least a five-diameter (stack) length fore and aft of the nozzle. Provision is made for heating the nozzle in cases where the gas sampled approaches the dew-point at the point of sampling. Thermometers T_1, T_2, and T_3 are inserted at locations shown.

Operation. Close slide gate of G and valves S and U, open valves V and Q and start cool water circulating through M. Start pump and regulate valve V (by closing) until pressure difference shown by manometer BB is zero. Read thermometers T_1, T_2, and T_3 as well as manometer AA and gage X. Repeat readings every 5 min. and collect and weigh condensate. At end of run collect and weigh dust (size by air elutriation or other means, if necessary). Flowmeter readings at temperature T_3 are corrected to temperature T_1 by allowing for increase of gas volume produced by a temperature change of $(T_1 - T_3)$° C. (the gas is assumed saturated with water vapor at temperature T_1). From weight of condensate per unit of time, the volume of water vapor per unit of time that must be added to the corrected flowmeter rates may be computed. The weight of dust per unit volume of gas is then readily calculated.

6. CUSTOM SAMPLING MILLS

A custom sampling mill is a plant comprising a series of crushers and sampling devices with suitable storage and transport accessories, all so arranged that the plant can receive ordinary run-of-mine rock in shipments up to several carloads, run the lot through the plant as a batch, and deliver a sample, and a reject more or less crushed as desired.

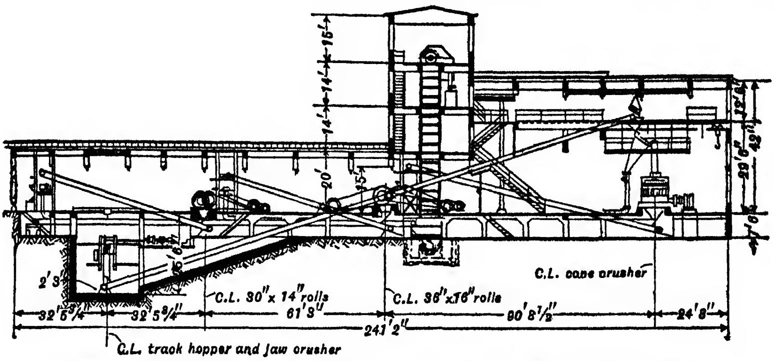

FIG. 60. One-level sampling mill, UTAH ORE SAMPLING Co. (see Fig. 62 for flowsheet).

Some sampling mills are run in conjunction with a mill and/or smelter, in which case they may buy the ore, or mill it on a custom basis (see Sec. 2, Arts. 25, 50). In such plants, if the ore is to be finely crushed for treatment, it may be broken to small size before samples are cut. Unless, however, the purchasing contract makes settlement compulsory on an umpire assay without resampling, such fine crushing of the lot must be done in the small crushers in the sampling plant with resulting loss in efficiency. If resampling is eliminated by contract, the lot can best be sampled in the mill at a point just prior to any division of the ore stream, all crushing thus far having been done in large mill crushers.

Arrangement of plant. Sampling mill construction of the early days was of the tower type wherein the building consisted of several floors; the ore was elevated by means of bucket elevators to the top of the building and was then allowed to pass through successive crushers and sampling devices, under the action of gravity, being finally delivered to the loading bins or platform. The chief objections to this type of construction are: (1) placing heavy intermittent machinery, such as a jaw crusher, on the upper floors, and (2) the use of bucket elevators, which are difficult to clean, and yet must be cleaned to prevent salting material subsequently sampled. Recent designs are mostly one-level type, using belt conveyors for elevation. Such mills are cheaper to build and simpler to operate; one crane can serve all machines; power distribution, attendance, supervision, and repair are all facilitated. Pulsifer (*121 P 866*) estimated that straight-line single-bay mills could be built 25 to 40% more cheaply than elevator-type mills. UTAH ORE SAMPLING Co. Unit D (Fig. 60) illustrates the one-level mill; the WASHOE plant (Fig. 61) the tower-type.

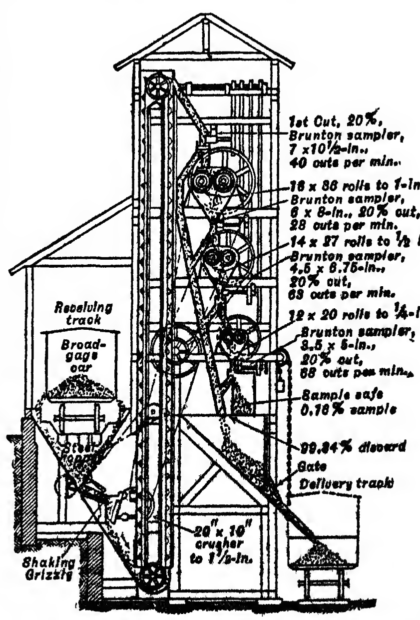

FIG. 61. Elevator-type sampling mill at WASHOE.

Flowsheet of a sampling plant comprises (1) crushing through some limiting size, (2) sampling at this size, (3) crushing the sample and again sampling, and (4) repetition of step (3) until a sample of the desired weight is obtained. The weight of sample taken at each stage is such as to bring uncertainty within the desired limits (Art. 1).

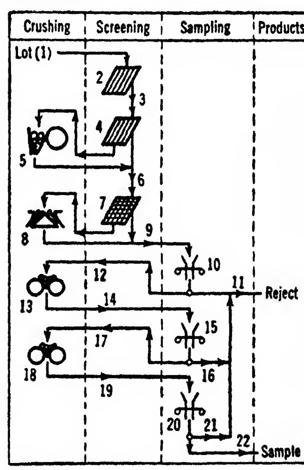
The machines used are of standard design. Primary crushers are jaw or gyratory (Sec. 4, Arts. 2, 3); reduction gyratories, or cones for intermediate crushing (Sec. 4, Art. 7); rolls or rod mills for finer crushing (Sec. 4, Art. 8; Sec. 5, Art. 7); samplers (Art. 7); conveyors and feeders (Sec. 18); screens (Sec. 7).

Flexibility of plant should be provided for in the design, since it is contemplated to handle materials differing widely in size and value. It should be possible to by-pass primary crusher with fine lots; or to by-pass one or more of the samplers when a small lot of material is to be sampled or when the ore is spotty. It is sometimes desirable to deliver a finer discharge, as when the shipment is to be sold to a concentrator, in which case crushing may be carried to ball-mill feed size prior to commencement of sampling.

Flow should be continuous and uniform, otherwise a given sampler may take no material during one or more revolutions and this failure may be multiplied in succeeding machines by synchronism, or two samplers may so synchronize for several revolutions that the second receives all of the sample cut by first. Any case between these extremes may occur, and in no case will the correct proportion be cut or the sample be representative. To avoid such contingencies, surge bins or feeders with some storage capacity should be placed between successive sample cutters.

Stoppage due to power failure or inadvertent throwing of a switch should not be accompanied by piling up of material, with spill and consequent loss or contamination. This may be prevented by suitable electric interlocks on the driving motors (see Fig. 63).

Accessibility. All parts of a sampling mill should be easily accessible for cleaning and observation. Housings on crushing and sampling machines should be detachable, and easily removable doors should be provided in all housings for elevators, chutes, launders, etc. Chutes and launders should be designed with minimum turns. Hoppers and bins should be constructed so that no material hangs up when they are emptied. Every precaution should be taken to avoid the possibility of clogging or leakage of material.



Legend for Fig. 62:

1. Shipments received in railroad cars.

2. Bar grizzly, 11-in. openings, located over track hopper (3); oversize sledged to pass.

3. 75-ton track hopper; discharge gate runs on roller guides and is actuated by gear and pinion from a free-running handwheel. 1 @ 36-in. steel pan-conveyor feeder inclined 6-i.p.f., driven by 2 @ 10-hp. slip-ring induction motors through a 256 : 1 gear reducer, so connected that 32 speeds in the range 4.5–1.3 r.p.m. are available, corresponding to a capacity range of 140 to 40 t.p.h.

4. Grizzly, 3-in. openings; fabricated entirely of manganese steel castings.

5. 1 @ 15×24-in. jaw crusher, 5-in. set, 250 r.p.m., 40-hp. motor.

6. 1 @ 24-in. belt conveyor with suspended magnet at head pulley; loading hopper and skirting designed to prevent spill and provide for quick clean-up.

7. Traylor vibrating screen, 3/8-in. aperture; feed checked by loose chains which help to prevent spill.

8. 1 @ 5 1/2-ft. standard cone crusher, 3/8-in. set, 490 r.p.m.; capacity at 3/8-in. is 100 t.p.h. Set varied as desired from 1 1/2- to 3/16-in.

9. 1 @ 24-in. belt conveyor.

10. 1 @ 6-in. Utah Ore Sampling Co. sampler (Fig. 38), 20% cut, 39 cuts per min.

11. 1 @ 18×8×8 1/2-in. bucket elevator, 400 f.p.m., 30-hp. motor; 1 @ 24-in. belt conveyor; 1 @ 125-ton reject bin so located over railroad track and 125-ton Fairbanks-Morse track scale that when cars are being loaded they are in weighing position.

12. Shaking feeder, 150 @ 3-in. s.p.m.

13. 1 @ 36×16-in. Traylor heavy-duty rolls, 3/16-in. set; power roll driven by 30-hp. motor at 75 r.p.m.; idling roll by 15-hp. motor; Tex-rope drives.

14. 18-in. belt conveyor.

15. 1 @ 3-in. Utah sampler, 10% cut, 43 cuts per min.

16. 18-in. belt conveyor.

18. 1 @ 30×14-in. Traylor rolls set to make <10-m. product.

19. 18-in. belt conveyor.

20. 1 @ 3-in. Utah sampler, 10% cut, 47 cuts per min.

21. 18-in. belt conveyor.

22. Delivered to a sample buggy securely housed in a sample vault.

Fig. 62. Utah Ore Sampling Co.

Cleaning between successive lots of ore is essential in order to avoid salting. Ordinarily compressed air and brushes are used for cleaning fine material from machines and spouts; floors should be swept and all material collected put with the lot just run through, or so disposed of as to preclude contamination of succeeding lots.

Dust losses. When a sampling mill has many open windows and a strong wind is blowing, the dust loss may be 5% of the total lot. As fine material is generally of higher grade than coarse, serious losses may thus occur. Further, it is hard to keep good labor in a dusty plant. Where hand sampling is employed, the ore is frequently dampened to keep down dust; this causes fine material to coat the larger pieces and thus aids in mixing. Wetting causes material to stick in automatic samplers and is, therefore, not permissible in sampling mills. Here all sampling machinery and crushers should be enclosed in dustproof housings, all chutes should be covered and free from leaks, and a dust-collecting system designed to deliver the dust from each lot sampled in one batch should be installed. If frequent observation of moving parts is necessary, small doors that can be readily opened, or coverings with removable sections, should be provided.

Utah Ore Sampling Co., Fig. 62 (*129 #5 J 233*).

Location: Murray, Utah.
Ores. From Park City, Tintic, and Murray.
Capacity 140 t.p.h. maximum.
Drive: Equipment is electrically interlocked (see Fig. 63) so that motors driving crushers, conveyors, and elevator can be started only in a sequence counter to the direction of the ore flow. By the use of relays and interlocking switches, failure of a motor automatically shuts down the motors of all conveyors preceding, but permits all succeeding equipment to function. Crushers are not stopped when the preceding conveyor stops.

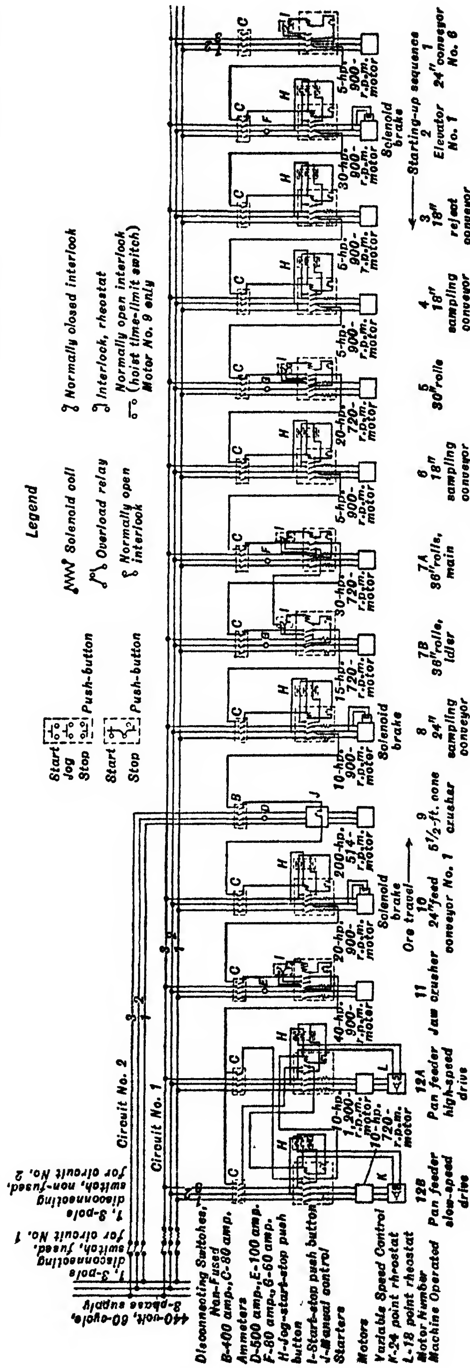

FIG. 63. Electrical interlocking system, UTAH ORE SAMPLING CO.

Summary. 2-stage crushing in open circuit to $^3/_8$-in., at which size sampling starts. 1 @ 20% and 2 @ 10% sample cuts with open-circuit roll crushing between stages; final cut at <10-m. Sample is 0.2% or 4 lb. per ton of feed. It is removed to a bucking room where it is further divided, dried, crushed, mixed, and subdivided until a final sample of about 3 lb. remains. MOISTURE SAMPLE is taken from the loaded cars under the reject bin by cutting numerous uniform trenches from the cones formed in the cars while loading.

Tacoma smelter (Fig. 64) shows the scheme of unloading from boats and sampling at Point Defiance, Wash. Ore is lifted from boats by 42-cu. ft. Brown-hoist bucket (*a*) and is dropped into hoppers (*m*)

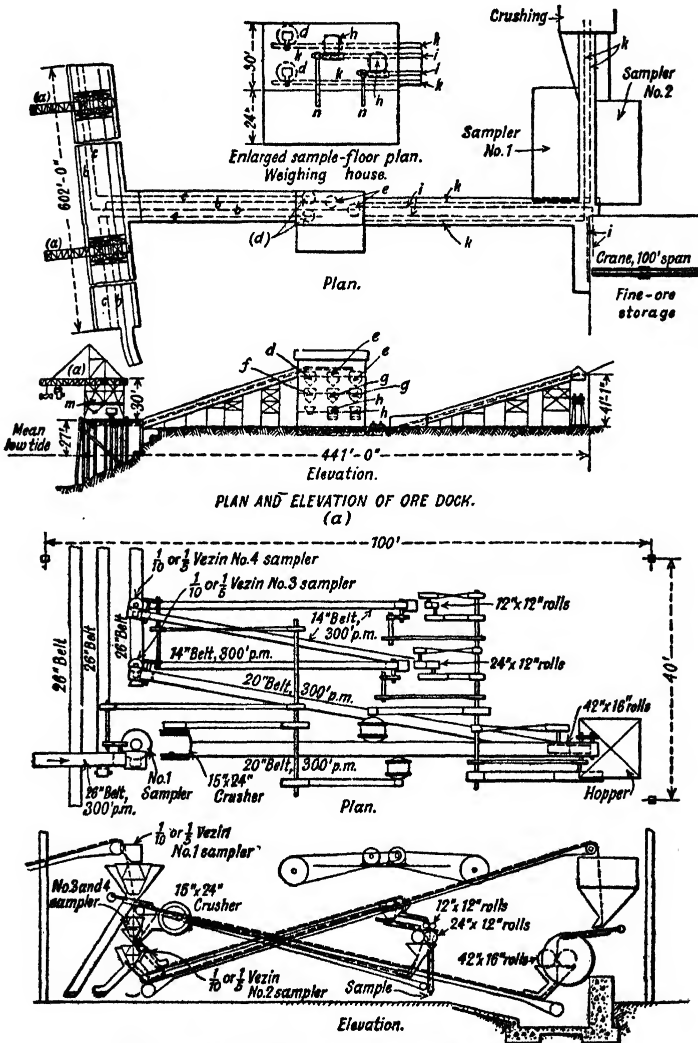

FIG. 64. TACOMA sampling plant.

feeding onto 24-in. belt conveyors (*b, c*). Conveyors (*b*) deliver concentrate to 550-cu. ft. hoppers (*e*), and conveyors (*c*) deliver coarse ore to 550-cu. ft. hoppers (*d*) in the weighing house. Directly below hoppers (*d*) and (*e*) are weighing hoppers (*f*) and (*g*) equipped with 60-ton Fairbanks-Morse recording scales. Concentrate passes from the weighing hoppers to Martin samplers (*h*) (Art. 3) which cut a 1/100 sample in two cuts of 1/10 each. The samples are delivered by belt conveyors (*n*) to the finishing

room for preparation of moisture and assay samples. Rejects from the Martin samplers are delivered to storage bins by conveyors (*i*). Ore after weighing is delivered to the sampling-plant bin by belt conveyors (*k*). The method of obtaining coarse-ore samples is shown in Fig. 64, item *b*, which, by variation in the percentage taken by each sampler, can deliver a final sample of 1/600 to 1/10,000 of the original lot. A large variety of gold, silver, and copper ores and concentrates is handled (*119 J 557*)

Bird Dog mill, Fig. 65 (*131 #8 J 351; 131 #2 J 49*).

Location: Ottawa, Okla.
Ore: Pb-Zn ore from three separate tracts leased from different owners.
Capacity: 110 t.p.h.
Storage: Daily output from each tract kept in a separate coarse-ore bin. Feed chute of sample bins co-ordinated with coarse-ore bins by central controller unit (p. 49).

Legend for Fig. 65:

1. Railroad cars weighed on a Howe track scale equipped with a Streeter-Amet automatic tape recorder discharge into 4-subsurface bins @ 200-ton, one for each ore, the fourth providing a reserve, each discharged by 36-in. apron conveyor.
2. 1 @ 30-in. jaw crusher, 4-in. set.
3. 1 @ 24-in. belt conveyor, 250 f.p.m.
4. Gate cutter, 10% cut, 1 cut per 3 min. (See p. 49.)
5. By rotating gravity chute (see p. 49) to 1 of 4 @ 50-ton bins, discharge taken by 1 @ 24-in. belt conveyor.
6. 1 @ 16-in. jaw crusher, 1-in. set.
7. 1 @ 12-in. belt conveyor.
8. Gate cutter, 10% cut every 30 sec.
9. 1 @ 12-in. bucket elevator.
10. Leahy vibrating screen, $^1/_2$-in. square aperture.
11. 1 @ 18-in. rolls.
12. Gate cutter, 10% cut every 14 sec.
13. 1 @ 12-in. belt conveyor.
14. 1 @ 18-in. bucket elevator.
15. 1 @ 800-ton bin.
16. Sample reduced by a cone sample grinder set at $^1/_8$-in., product riffled to give a 75-lb. assayer's sample.

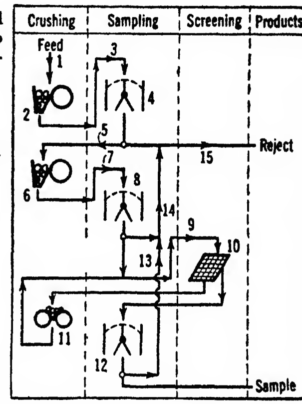

FIG. 65. BIRD DOG MILL.

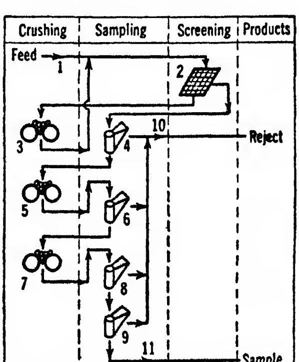
Summary. Single-stage crushing in open circuit to 4-in. at which size sampling begins; 3 @ 10% sample cuts with crushing between stages, final cut on undersize of $^1/_2$-in. screen closing circuit on final crushing stage.

Hecla Mining Co., Fig. 66 (*IC 6600*).

Location: Gem, Idaho.
Ore: 8.7% Pb, 4.8 oz. Ag, 1.2% Zn.
Capacity: 900 t.p.d. maximum.



Legend for Fig. 66:

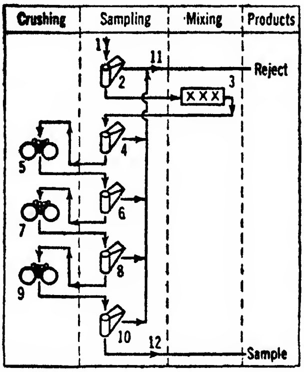
1. From coarse crushing and sorting plant.
2. 1 @ 36×60-in. trommel, 30-mm. aperture.
3. 1 @ 42×16-in. Garfield rolls.
4. Vezin, 10% cut.
5. 1 @ 26×15-in. rolls.
6. Vezin, 10% cut.
7. 1 @ 24×12-in. rolls.
8. Vezin, 10% cut.
9. Vezin, 10% cut.
10. To mill.
11. About 150 lb.; 0.01% sample riffled to assay size.

FIG. 66. HECLA MINING CO.

Summary. Closed-circuit roll crushing to 3-mm. at which size sampling starts, 4 @ 10% sample cuts with open-circuit roll crushing following first and second stages. Despite large primary sample cut at relatively small size and high total percentage taken for final sample, results are erratic.

Old Dominion, Fig. 67 (*IC 6467*).

Location: Globe, Ariz.
Ore: Copper.
Capacity: 1,500 t.p.d.
Sampling mill: Built in 1914 when company treated custom ores, then adapted to sample company ore and lime.



Legend for Fig. 67:

3. Mixing barrel, 12 r.p.m.
4. Vezin, 21 r.p.m., 20% cut.
5. 1 @ 36×16-in. A-C rolls, 72 r.p.m.
6. Vezin, 32 r.p.m., 20% cut.
7. 1 @ 28×14-in. CIW rolls, 150 r.p.m.
8. Vezin, 23 r.p.m., 20% cut.
9. 1 @ 12×12-in. CIW rolls, 150 r.p.m.
10. 2-Vezin samplers, 25 r.p.m., each taking a 10% cut of stream.
11. Reject by 12-in. elevator to storage.
12. Original and duplicate samples, each 0.008% of original material.

FIG. 67. OLD DOMINION.

Summary. Five stages of sampling, 1 @ 10% followed by 4 @ 20%, with open-circuit roll crushing between last four stages and mixing after first stage.

Portable sampling mill, designed by the U.S.B.M. (*IC 6545*) for coal sampling on location, consists of a truck on which are mounted a swing-hammer crusher with 20-hp. gasoline-engine drive. Crusher is fitted with 3/16-in. gratings and run at 1,100 r.p.m. Crusher product is divided by a 12-chute riffle, which is supported when in service by arms hooked onto the chassis frame under the crusher. Sample is collected in tubs slid under riffle spout, which is 19 in. above road; reject falls to the ground. Crusher is cleaned by compressed air at 100-lb. pressure supplied by a small compressor mounted on the truck. Capacity is about 1,000 lb. per hr.

7. PREPARING SAMPLES FOR ASSAY

The problem involved in preparation of samples for assay is to reduce them to a particle size that will justify cutting out an assay sample weighing, ordinarily, between 1 and 30 gm. and that will be fine enough to dissolve or otherwise yield its values completely within a reasonable time. These requirements are ordinarily interpreted to require a particle size of 65-m. limiting or smaller. Hence, since head samples, almost invariably, and other samples, frequently, are much coarser than this, and their bulk is too great to justify reduction of the entire sample to such a particle size, procedure is to follow a plan of successive size reduction and sample cutting similar to that of a custom sampling mill (but in most cases on a much smaller scale) until from 1 to 5 lb. only is left for grinding to assay size. If the mill sample is large, it will normally be run down by machine, as in the custom mill; if small (a few tons) it may be run down by hand, although a one- or two-stage sampling mill run batch to reduce to 100 lb. or less is normal unless labor is very cheap; lots of 100 to 500 lb. are ordinarily crushed in small hand-fed machines and sampled by hand methods.

Marking samples. In custom-sampling mills, where many different lots are run in succession through the mill, ample provision must be made to avoid possibility of confusion of samples. A satisfactory method is to keep a complete record of the treatment of each lot on a suitable form convenient for filing. This form should accompany each sample until the work is finished and the sacked sample delivered to the assayer. It should then be filed for permanent record In mill work, when samples are of small bulk and can be held in pails or pans, small numbered tags of copper or brass are convenient for identification. Complete record of identity of sample is kept in a notebook record on a form numbered the same as the pan or pail.

Samples in sacks may be marked with linen or paper tags. If there is danger of the tags becoming wet, a thin coating of hot paraffin or shellac will prevent the marking on the tag from being obliterated or changed.

Assay-office Procedure

Samples delivered to the bucking room or assay office range in weight from a few pounds to 100 lb. Pre-assay procedure usually comprises drying, and coarse and fine grinding as required.

Drying is done in ovens or on stoves or hot plates. Steam, electricity, or burning coal, wood, gas, oil or other material may be used to furnish heat. Exhaust-steam tables are particularly desirable. Steam is usually circulated through coiled pipes arranged in shelves on which the sample pans are placed, or through false-bottom steam tables on which samples are dumped. (See Fig. 164.)

Dewatering of wet-pulp samples is done by decanting, siphoning, or filtering, final drying in any case being by evaporation. Suitable flocculating agents may be used to settle solids before decanting or siphoning. (See Sec. 15, Art. 3.) Pressure, vacuum, or gravity filters are used. Where the amount of sample for a definite period is large, a series of small settling tanks may be used, arranged so that each succeeding one takes overflow from the preceding, overflow from the last being clear. Final dewatering of material remaining in the tanks is done by evaporation, preceded, if necessary, by filtration. Dewatering before evaporation must not be practiced, if metals are in solution, unless separate solution assays and moisture determinations are made. Great care must also be required of operators in decanting and siphoning to prevent slime losses.

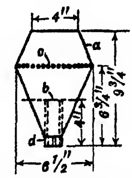

FIG. 68. Rotor for moisture-sample dewaterer.

Moisture-sample dewaterer shown in Fig. 68 was designed for use with the wash iron ores of the Mesabi Range (*140 #6 J 56*). It comprises a conical centrifugal rotor *a* with a conical sample container of the form shown. A false bottom *b*, consisting of a solid metal disk, is welded into the lower cone, and 1/8-in. holes *c*, spaced 1/4 in. apart, are drilled around the periphery. Sleeve *d* fits over a 1-in. shaft flexibly connected to the shaft of a vertical 1/2-hp., 1,725-r.p.m. motor controlled by a time switch. A rectangular housing with an upsloping pyramidal bottom cut out for the lower cone surrounds the rotor and leads extruded water to a drain. The sample is crushed to 1/4-in., riffled to 1 kg. and centrifuged for 7 min. Water expulsion is 95% complete in 1 min., 99% in 2 min. Little ore is lost.

Maximum temperature at which drying is done varies in different plants reporting from 132° F. to 450° F. Temperatures around 200° to 220° F. are most generally used. Ordinarily it is best not to use temperatures above 212° F. on account of danger of loss. This is especially true with easily oxidized sulphide ores which may lose sulphur on heating, or with minerals containing water of crystallization. In some cases temperatures even lower than 212° F. may be necessary, as in the case of certain clays in which water of crystallization is driven off before all hygroscopic moisture has evaporated. For air-drying samples for moisture determination the U. S. Bureau of Mines uses a temperature of 35° C. (95° F.).

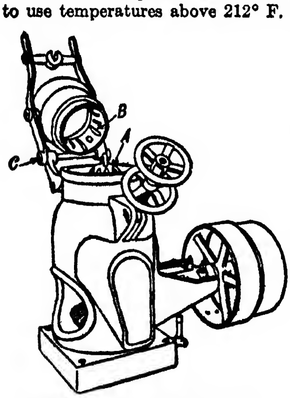

FIG. 69. Engelbach grinder.

Test for completion of drying may be made by holding a cool, dry watch glass or plate over the sample. Absence of condensed vapor on the glass indicates that the sample is dry. Stirring a hot sample with a spatula gives an indication of the presence of moisture by the vapor which rises. The most accurate test is to weigh until no further loss in weight takes place on further heating.

Crushing samples. Small jaw crushers are best for crushing material from 1- or 2-in. maximum down to about 0.5-in. Either the Blake or Dodge type is satisfactory. Small gyratory crushers may be used. Intermediate grinding is generally done in a COFFEE MILL (Engelbach; Fig. 69) in which grinding is done between a rotating cone *A* mounted on a vertical, gear-driven spindle and stationary circular concaves *B* attached to the machine. The grinder is arranged so that the top part, containing the concaves, may be lifted on hinges *C* allowing access for cleaning and repairs. The following sizes may be obtained:

Capacity lb. per hr.	From	To	R.p.m.	Power required, hp.	Approx. weight, lb.
200	0.5-in.	10-m.	225	4	850
100	0.375-in.	10-m.	250	3	550

Fine grinding of samples is best performed in DISK GRINDERS of either the Braun (Fig. 70) or McCool type.

Braun pulverizer. The ore is ground between two disks, one revolving (*a*) and the other stationary (*b*); fineness of product is determined by adjustment of screw *c*. The revolving disk is mounted on a horizontal shaft equipped with tight and loose pulleys *d*. Material is fed through hopper *e* and enters the space between the disks at the center whence it is fed by gravity and centrifugal force to the periphery and there ground. Ground material passes between the disks and is discharged into a removable tray *f* beneath. Removable cover *g* and the hinged stationary disk permit easy access to the grinding parts for cleaning. Feed may be 1/4-in. size. The principal dimensions are: length, 23 in.; width, 14 in.; weight, 235 lb., 850 r.p.m.; 1 hp. One set of grinding disks should handle from 2,500 to 7,500 ordinary ore samples. They are readily replaced.

McCool pulverizer is a similar machine except that slow relative motion of the disk centers is superimposed on rotation, which is supposed to accent the rubbing motion between the disks. The machine is made in two sizes, the larger rated at 1 lb., the smaller at 0.5 lb. to 100-m. in 30 sec.

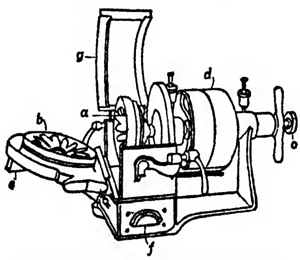

FIG. 70. Braun disk pulverizer.

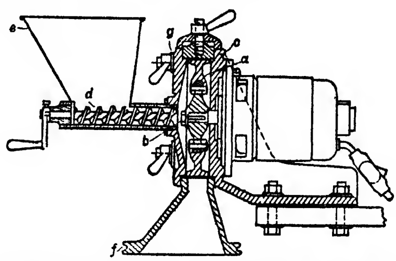

FIG. 71. Laboratory hammer mill (*Raymond Pulverizer Co.*).

Hammer mill (Fig. 71). Ore is broken by impact with hammers (*a*) mounted on a horizontal shaft *b* making 10,000 r.p.m. This mechanism is enclosed in a cylindrical chamber *c*, lined at the bottom with a screen; a hand-operated screw conveyor *d* provides controlled transport of feed from hopper *e* to mill. Screen undersize drops through an air-filter cloth tube attached to *f* into a suitable sample container. Removable cover *g* permits easy access to mill for cleaning and changing of screen. Stainless-steel screens with circular apertures of 0.024-, 1/16-, 1/8-, and 1/4-in. diameter are provided; a fine screen with rectangular aperture $0.010 \times 15/32$-in. is also available. Applicability is limited to soft, friable materials.

Bucking board consists of a flat cast-iron plate with finished surface on which ore is pulverized by means of a cast-iron muller on a wooden handle. The operation is usually manual, but mechanical drive may be used, if desired. Bucking boards are not as efficient or quick as disk grinders but furnish suitable means for grinding in places where power and more elaborate equipment are not available or for grinding very small quantities of material that might be lost in a mechanical grinder.

Grinding surfaces should be of material that is not so hard that it becomes polished, with consequent reduction in efficiency, nor so soft that the value of the sample is affected by admixture of fragments from the surfaces. If the surfaces are very soft, pieces of valuable mineral may be taken up, thus not only reducing the metal content of the sample being ground, but possibly salting succeeding samples. Grinding surfaces developing small holes or cavities should be avoided and discarded. Filling such holes with soft metal should not be practiced. Iron introduced into a sample by grinding can be removed with a magnet, if objectionable.

Fineness of sample required for assay varies with the character of ore. Since the actual material assayed must be cut out of the assay sample, the maximum size of grain must bear the same relation to the weight of the sample cut as at any other step in the sampling operation. Further, where a wet method of assay is employed, grinding must expose all of the valuable mineral to the action of the solvent. Usually a large factor of safety is allowed in the final sample and no sample for assay is coarser than will pass 65-m.; many plants pass the final sample through 100-, 150-, or 200-m. before delivering to the assayer.

Procedure in final grinding is to pass the sample through the grinder and separate undersize through a screen of the desired aperture. Oversize is returned to the grinder and the operation repeated until all passes the screen. Iron washers or stiff brushes are frequently used to aid in pushing material through the screen. Time is thus saved but washers cause wear on screen wires and in case of ores containing fine elongated pieces of valuable metal or mineral a piece may be forced through the screen that will have a serious effect on the value of the sample. With ores containing metallics it is often found impossible to pass the last flat metallic pieces through the screen, even on repeated grinding. In such cases the final oversize of metallic pieces is collected, weighed, and assayed separately, and its value is allotted in proportion to its weight and the weight of the sample. The screens used should be perfect.

Cutting down samples. See Figs. 8 to 13, 17, 24, 25, and accompanying text.

Mixing is essential before dividing a sample or weighing out for assay. Simple methods are usually employed: (*a*) coning; (*b*) turning over and over with a spatula; (*c*) rolling

on a piece of glazed paper, rubber or oilcloth. Rolling is accomplished by drawing the corners of the paper or cloth horizontally toward diagonally opposite corners, causing the sample to roll over and over on itself. If the corner is lifted instead of drawn horizontally, the sample merely slides along the surface of the cloth and no mixing occurs. (*d*) ANACONDA MIXER, consisting of a cubical box rotating on a horizontal axis forming a diagonal of the box, makes an efficient mechanical mixer for small samples; (*e*) JONES RIFFLE may be used for mixing finely ground material, the two portions obtained being united and passed through again and again.

Final division of ground samples into small parcels for assay may be effected by riffles or machines as described above, or by one of the following methods: (*a*) Coning and quartering. (*b*) Spreading and taking small portions with a spatula from points scattered at random over the surface of material, taking care that the spatula tip goes down to the bottom of the pulp layer each time. (*c*) Pouring into bottles from a rolling cloth or scoop after mixing, using a bottle-filling device comprising a trough compartmented transversely into, say, four compartments, with corresponding delivery spouts fitting into wide-mouthed bottles. (*d*) Mechanical dividers of various types, usually diminutives of apparatus already described. (*e*) A method including mixing and dividing, successfully used on COBALT silver ores (*17 CMI 199*) is as follows:

The finely ground sample (<100-m.) is sifted several times through a 40-m. screen onto a glass table, the screen being held about 2 in. above the material on the table. The pile is kept spread with a spatula. The glass table is marked off radially from a center into 16 equal sectors, and the material sifted is centered. After the final sifting the material is divided along radial lines. Material from alternate sectors is placed in separate packets, thus giving eight samples for such disposition as is desired. The balance of the material is rejected.

8. COST OF SAMPLING

Information on costs is limited and of such character that averages are of little value. Costs vary with the character and value of ore, nature of the operation, location of plant, cost of labor, tonnage sampled, and whether ores are purchased or not, the desired size of the reject, etc. Custom sampling costs from 15 or 20¢ to 75¢ or $1 per ton according to the efficiency of the plant, the daily tonnage, and the character of the ore. Charges are, of course, higher (see Sec. 2, Art. 50). Table 24 gives costs and other available pertinent data for a number of mills.

Table 24. Costs of sampling at milling plants

Mill	Location	Ore	Date	Tonnage per day	Sampling costs, $ per ton	% of milling costs
Mount Isa	Australia	Pb-Zn	1939	*e*	0.013	1.4
Morenci	Ariz.	Cu	1931	5,000	0.015–0.014 *a*	2.6–2.7
Old Dominion	Ariz.	Cu	1931	1,500	0.044 *a*	6.3
Utah Copper, Arthur and Magna mills	Utah	Cu	1931	30,000	0.00417 *a*	1.38
Kirkland Lake Gold Mines	Ont.	Au	1931	142	0.0165 *a*	1.2

a Sampling plus assaying.
b 60% of this cost chargeable to labor.
c Operating labor, 0.0576; maintenance labor, 0.0059; supplies, 0.0185; power, 0.0099.
d 0.0124 labor, 0.0022 supplies, and 0.0059 power.
e 2,650 t.p.d. for mixed oxide-sulphide ores, 1,880 t.p.d. for straight sulphide ores.

TESTING

Laboratory testing in connection with ores and industrial minerals has always one of two ends in view, *viz.*, (*a*) determination of the nature and/or behavior of material, or (*b*), determination of the character and/or action of a machine or process.

Tests on the nature of a material have to do either with inherent properties, *e.g.*, identity, specific gravity, magnetic permeability or solubility; or with accidental or ephemeral

properties such as size or surface character. Tests of behavior are ordinarily directed toward determination of movement under given conditions, *e.g.*, sedimentation rates or inertial movements in particular apparatus; or toward chemical behavior in special environments.

Tests of apparatus and processes may be directed simply toward determination of the behavior of a given material in a given machine or process, or may deal more generally with the fundamentals of action of the method or apparatus.

Methods of testing are almost as diverse as the materials, processes, and apparatus tested, but they may be classified into two main groups with a relatively small number of sub-groups as follows:

I. ***Tests for nature of material.*** (*a*) Optical, using the microscope, camera, and special means of illumination. Use of short-wave energy apparatus, such as the X-ray and electron microscope, is beginning in the ore-dressing field, but apparatus and techniques are not yet sufficiently simplified to justify inclusion of such apparatus in other than a few research laboratories where the services of skilled technicians in these fields are available. (*b*) Chemical and electrical. (*c*) Resistance to comminution. (*d*) Sizing. (*e*) Gravitational.

II. ***Tests of machines and processes.*** (*a*) Behavior of a given material subjected to a given process or machine. (*b*) Effects of variations in operation of a machine or process on its performance. (*c*) Nature of a process, *i.e.*, the way it utilizes fundamental physical and/or chemical phenomena.

9. OPTICAL TESTING

Introduction. Optical methods of testing provide means for (*a*) extending the range of vision of small particles and fine structures to sizes of the order of 0.1-μ (the electron microscope goes to 0.001-μ and the X-ray to atomic dimensions); and (*b*) speeding up visual perception to the point at which motion at velocities of 36 mi. per min. at a distance of 12 in. from the camera lens (12-in. focal length) can be stopped satisfactorily, or slowed down to an extent that permits normal visual observation and comprehension.

Microscopes

Utility of the microscope in an ore-dressing laboratory is tremendous; no laboratory that makes any pretense to thorough ore-testing or process research can get along without three or four different types; detail as small as 0.0000005 cm. is rendered visible by an electron microscope, and as fine as 0.00002 cm. with a compound microscope, whereas the unaided eye can only distinguish detail coarser than 0.01 cm.

Essential elements of the compound microscope are: (*1*) the CONDENSER, which collects and concentrates light upon the object under observation; (*2*) the OBJECTIVE, which receives light from the object and compounds therefrom a primary enlarged image of the object; and (*3*) the OCULAR (eyepiece), which forms a secondary enlarged image of the primary image.

Types of microscopes may be classified according to the interaction of the light with the object as (*a*) TRANSMITTING TYPES, used for examination of transparent objects, and (*b*) REFLECTING TYPES, used for opaque objects. Each type has two sub-types according as the light used is ordinary (for examination of isotropic and anisotropic materials) or polarized (for anisotropic materials). Standard equipment in an ore-dressing laboratory should include at least: a Greenough binocular, a biological or research instrument, a metallurgical miscroscope, and a petrographic microscope. Instruments of these types may be purchased from any of the manufacturers of such equipment. (Bausch & Lomb Optical Co.; E. Leitz, Inc.; Pfaltz & Bauer, Inc.; C. Reichert Optical Works; Spencer Lens Co.; Carl Zeiss.) The descriptions of instruments and procedures that follow are limited, particularly with respect to optical accessories. As the operator becomes proficient in the basic uses of a particular instrument, he should consult the manufacturers' catalogues and the literature of microscopy to acquaint himself with the available accessories and variants of procedure which enhance the utility of the instrument.

Selected bibliography of microscopic theory and practice: E. Spitta, *Microscopy*, John Murray, London, 1920; C. Beck, *The Microscope*, 2 vols., R. & J. Beck, Ltd., London, 1924; J. Belling, *Use of the Microscope*, McGraw-Hill Book Co., 1930.

Binocular microscope (Greenough type) is a compound microscope of relatively low total magnification, useful for both transmitted and reflected work; it is the usual first step in magnification beyond the pocket lens. It is characterized by the stereoscopic image obtained by the use of two objectives slightly inclined to each other.

Stand (usual form) comprises horseshoe base *A* (Fig. 72, item *a*) carrying tiltable platform *B* on axis *C*, fixed in any desired position by tightening nut *D*. Stage *E*, fastened to *B* by screws *F*, carries pillar *H*, which is grooved to receive arm *J*, and is equipped with a pinion, actuated by pinion heads *I*, which engage rack *K*. Arm *J* carries a revolving-drum nosepiece *L*.

Stage E is equipped with a removable glass insert *M* (used for transmitted work), and a removable metal plate, white on one side, black on the reverse (used to get contrast in reflected work). Clips *N* hold objects in position. Arm rests *G* (optional) serve to steady hands while working.

Stand shown in item *b* is useful for examination of parts of large objects.

Optics comprise (*a*) mirror *O* (plane one side, concave the other), which receives light from the illuminant and directs a parallel or convergent beam upward through *M*; (*b*) paired parfocal objectives *P*, mounted on *L*, with COMPONENT MAGNIFICATIONS (magnification of primary image) of 0.39×, 0.7×, 1.5×, 2.0×, 3.0×, 4.0×, and 7.5×, so designed that when the instrument is focused on object and another objective is swung into place no change of focus occurs; (*c*) paired oculars *Q* (one with a correction collar *S*), mounted in body tubes *R*, adjustable as to interpupillary distance so that a single

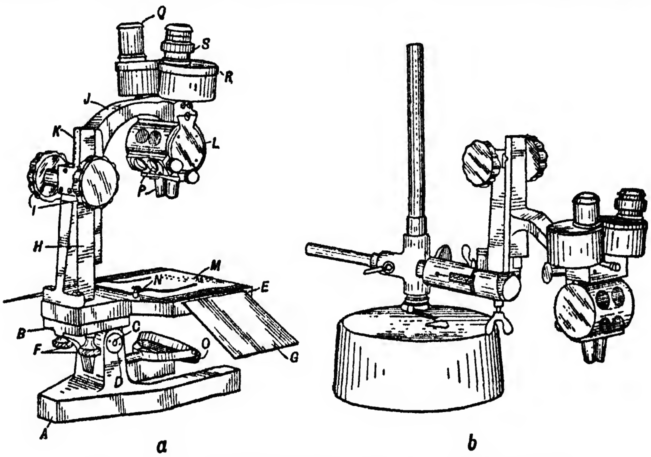

FIG. 72. Greenough binocular microscope (*Bausch & Lomb*).

image may be seen by different observers. OCULAR COMPONENT MAGNIFICATIONS (additional magnification imposed on primary image when secondary image is formed by ocular) are 10×, 15×, and 20×. Oculars have a large field of view, high EYEPOINT (point at which eye must be placed to view image), and good definition to the edge of the field.

Operation for transmitted work. (*a*) Place transparent object, mounted or unmounted, on stage glass. (*b*) Adjust light source so that its rays fall on mirror. (*c*) Turn mirror to direct light onto object. (*d*) Turn low-power objective into view position and rack objective down to within 1/2 in. of high point of object. (*e*) Rotate body tubes to suit interpupillary distance. (*f*) Rack objective upward until image is seen (rough focus). (*g*) Adjust interpupillary distance (if necessary) so that a single image is seen. (*h*) Sharpen focus and adjust mirror until field appears uniformly illuminated.

Operation for reflected work. (*a*) Place object on metal insert, using side producing maximum contrast. (*b*) Arrange illuminant to cast beam directly on object. (*c*) Proceed as in *d*, *e*, *f*, and *g* for transmitted work. (*d*) Sharpen focus. (*e*) Adjust illumination (or orientation) to give required contrast and to cast shadows in desired direction. For FLAT LIGHTING (producing no shadows) see Fig. 80, item *b*. Oblique lighting with shadow detail is obtained by opposing principal illuminant by another light source directed toward the shadow side of the object; the distance of the secondary source from the object determines the amount of shadow detail.

Balancing the optical system. (*a*) Focus on an object and adjust interpupillary distance. (*b*) Place a shield over the ocular with correction collar *S* (Fig. 72), and sharpen focus by use of pinion heads *I*. (*c*) Transfer shield to other ocular and sharpen focus by rotating correction collar.

Troubles. If operator is unable to see a single image, assuming proper adjustment of interpupillary distance, the eyes may be assisted to accommodate by viewing intently any object held at a distance of 10 in. therefrom, then quickly applying eyes to oculars without changing the eye focus. Dust spots that rotate when the oculars are rotated are on the oculars, otherwise on the objective or body tube. Remedy is to clean the offending member (see p. 77). If cleaning of external surfaces does not remove the source of trouble, the ocular may be disassembled and the elements cleaned, but the body tube and objectives should be cleaned only by a professional optician.

Utility of the binocular microscope lies in the three-dimensional image yielded; it is limited by the relatively low TOTAL MAGNIFICATION (ocular component magnification × component magnification of objective) and low resolving power (see p. 74). It is most frequently used in examination of hand specimens, mineral fragments, products of concentration processes, filter cloth and cake, processes in operation, etc.

Research microscope for transmitted work is a compound microscope capable of total magnifications ranging from about 50× to 2,000×; it is characterized by great flexibility and range in the system of illumination. Its particular field is in examination of liquid-solid mixtures.

Stand (Fig. 73, item *a*) consists of limb *A* tiltably mounted on foot *B*, and carrying body tube *D*, illuminating apparatus *E*, and stage *F*. Coarse focusing is done by milled heads *H*, position may be clamped by lever *J;* fine focus is by *G*. The body tube is clamped to block *I* by lever *K;* it is provided with revolving nosepiece *L*, which carries three (or four) objectives *M*, and either the inclined binoculars *N* or an erect or inclined monocular.

Stage plate *O* is moved backward and forward (50-mm. range) by pinion head *Q*. Grooved slide *R* is moved laterally (75-mm. range) by pinion head *S;* it carries two fingers *T* for holding specimens.

Illuminating apparatus (item *b*) is provided with a rack and pinion *U* for focusing the illuminating beam. Sleeve *V* holds condenser *W*. Iris diaphragm *X* is movable horizontally by rack-and-pinion movement actuated by *Y;* it is rotatable on base *AA*, and swings in and out on pin *BB;* aperture is controlled by lever *Z;* a shoulder immediately below the leaves supports filter disks (if desired).

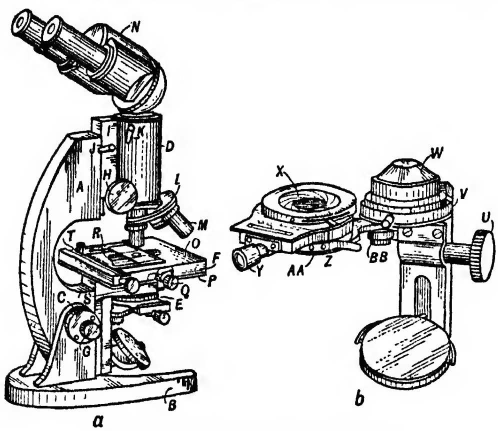

FIG. 73. Research microscope (*Zeiss*).

Optics of the compound microscope consist of the objective, ocular, condenser, and aperture diaphragm.

Objectives are classified, according to the extent of the optical defects of the lens system, as achromatic, fluorite, and apochromatic objectives; the principal optical defects being spherical and chromatic aberrations. SPHERICAL ABERRATION is due to noncoincidence of the foci of rays passing through the marginal and central elements of the lens; CHROMATIC ABERRATION is due to the noncoincidence of the foci of the differently colored rays produced when white light passes through the marginal elements. ACHROMATIC OBJECTIVES are corrected for two colors in chromatic aberration and one color (olive-green) in spherical aberration. APOCHROMATIC OBJECTIVES are corrected for three colors in chromatic aberration and two colors in spherical aberration. Fluorite (SEMIAPOCHROMATIC) objectives are corrected to an intermediate degree.

Numerical aperture (N.A.) of an objective is a measure of its light-gathering power; N.A. $= \mu \sin \theta$ where μ = refractive index of the medium intervening between object and objective and θ = one-half of the angle subtended by the front lens of objective at the object. Objectives ranging in numerical aperture from about 0.15 to 1.60 are available. Objectives with numerical apertures up to 1.00 are used with air as the intervening medium and are known as DRY OBJECTIVES. IMMERSION OBJECTIVES (N.A. $\geq$ 1.00) require the use of a fluid between object and objective; water for white light for N.A. = 1.25; glycerine (used for ultraviolet light) for N.A. = 1.25; cedarwood oil for N.A. 1.00∼1.42, and α-monobromonaphthalene for N.A. = 1.60.

Resolving power of an objective, measured by the distance x between two points of the object which are just separated as two distinct points in the image, depends upon the N.A. of the objective, the wave length λ of the light employed, and upon the method of illumination, *i.e.*, $x = \lambda/\text{N.A.}$ for axial illumination and $x = \lambda/2\ \text{N.A.}$ for oblique illumination.

Depth of focus of an objective is that distance perpendicular to the object plane throughout which all object details appear in sharp focus in the image. Depth of focus $D = R\mu/M\ \text{N.A.}$ where M = magnification of the objective, and R is the limit of resolution of the eye (0.01 cm.).

Cover-glass thickness to be used with a particular objective depends upon the design of the objective and differs for the products of the different manufacturers (Bausch & Lomb, 0.18 mm.; Leitz, 0.17 mm.; Spencer, 0.18 mm.; Zeiss, 0.17 mm.). Use of cover glasses of thickness other than that recommended introduces spherical aberration in the image. With cedarwood oil as the immersion medium, close adherence to recommended thickness is not too important (provided ample working distance exists), since the oil and glass form an optically homogeneous stratum between object and objective. With objectives of low numerical aperture ($\leq$0.30), cover glass thickness may vary within wide limits (cover glass may even be omitted) without appreciably affecting quality of the image. Some objectives are equipped with a correction collar graduated in millimeters of cover-glass thickness. For an unknown cover-glass thickness, the correction collar is properly adjusted when the image goes out of focus at the same rate at which it comes into focus. When objectives with correction collars are not available, variations in cover-glass thickness may be compensated by changes in optical tube length (see below), decreasing tube length if cover glass is too thick, increasing if too thin.

Optical tube length (distance between back focus of objective and front focus of ocular) to be used with an objective varies with the manufacturer; Bausch & Lomb, Spencer, and Zeiss objectives require a tube length of 160-mm.; Leitz and Winkel-Zeiss use 170-mm. Optical tube length is determined by setting of mechanical tube length.

Oculars may be classified according to intended use; class names vary among the manufacturers. Huygenian eyepieces with component magnifications ranging between 4× and 15× are used with achromatic objectives of low N.A. (≤0.30 to 0.40). COMPENSATING OCULARS (3× to 30×) are designed to compensate the chromatic aberrations existing in the primary image of apochromatic objectives, hence must always be used therewith. Compensating eyepieces may also be used with the highest power achromatic and fluorite objectives. HYPERPLANE (Bausch & Lomb), ORTHOSCOPIC (Zeiss), and PLANOSCOPIC (Spencer) oculars (5× to 30×) are designed for use with high-power achromatic and fluorite objectives; they yield a flatter image plane than Huygenian oculars.

Condensers may be divided into two classes, (*A*) condensers used to produce axial (or oblique) illumination, and (*B*) condensers used to produce dark-field illumination. Many condensers for axial illumination are available; the better known and most widely used are (*a*) concave mirror, (*b*) Abbe (least corrected optically), (*c*) achromatic (corrected for two colors in chromatic and spherical aberrations), and (*d*) aplanatic (intermediate optical correction). The better known dark-field condensers are the paraboloid and the cardioid.

Numerical aperture of condensers is defined and dependent upon the same quantities as for objectives (see p. 74); the refractive index here refers to the medium intervening between the condenser and the object slide (SLIP). Condenser apertures range between 0.3 and 1.40. Axial-illumination condensers are so constructed that by unscrewing the top element (or elements) the N.A. is reduced. When used at aperture >1.00 the condenser should be oiled to the slide. APERTURE DIAPHRAGM provides means for controlling the N.A. of axial-illumination condensers and for producing oblique illumination.

FIG. 74. Types of illumination.

Types of illumination attainable with the research microscope are: (*a*) axial, (*b*) oblique, and (*c*) dark-field.

Axial illumination (Fig. 74, item *a*) is characterized by symmetrical disposition of illuminating rays about the optical axis *G*, and is obtained by placing the center of *F* on the optical axis. It differs from dark-field illumination in that the illuminating rays enter the objective. It images plane object areas perpendicular to the instrument axis white, while such areas making an angle <90° with the axis appear shaded; consequently details in inclined areas tend to be obscured. The outline of the object is rendered sharply provided there is a sufficient difference between the indices of refraction of the object and surrounding medium. This type of illumination is used for general purposes with transparent materials, *e.g.*, examination of size, shape, color, etc., of transparent mineral fragments, and examination of thin sections.

Oblique illumination (Fig. 74, item *b*) is obtained by displacing the aperture diaphragm from a position of symmetricality, and is characterized by unsymmetrical disposition of the illuminating rays. It should be noted that every sector of the objective receives light (after interaction with object) even though object is illuminated from one side only. Such illumination produces shadows in the image, which give the image a third-dimensional effect that greatly simplifies recognition of geometric shape; it does for the axial image what relief does for a contour map. Examination of crystalline reaction products in chemical microscopy is an excellent illustration of its use.

Dark-field illumination (Fig. 74, items *c* and *d*) is characterized by nonentry of illuminating rays into the objective. Dark-field illumination images plane object areas perpen-

dicular to the axis black; areas otherwise inclined appear illuminated. The resolving power of the instrument is doubled with this type of illumination; hence it separates structure details not resolvable by axial illumination. It is used to examine details in inclined areas such as the sides of pits and protrusions in transparent materials; it has wide use in examination of suspensions of fine particles.

Adjustment for axial illumination differs depending upon whether the primary or some secondary light source (such as the light condenser) is imaged in the plane of the object (Fig. 75). Both methods seek to fulfill the conditions of critical illumination, *viz.*,

FIG. 75. Critical illumination.

(*a*) attainment of illuminating rays symmetrically disposed about the optical axis and capable of entirely filling the area of the back lens of the object without exceeding this area, (*b*) uniform illumination of object limited to the area under view. The means for limiting the area illuminated is a field diaphragm *L*, which is placed as close to the light source *P* as is physically possible, so that it forms an image in the object plane *G* when *P* is imaged therein. The first method (item *a*) is applicable only when the light source contains a uniformly radiating element (ribbon-filament lamp or the like). In this case, the light condenser *M* is so situated as to produce a parallel beam of light (*P* at principal focus of *M*). When *M* is used as the secondary source of light (item *b*), *L* is located immediately in front of it, and *P* is placed beyond the principal focus of *L* so as to produce a convergent beam of light which comes to a focus in the aperture diaphragm *J*.

To image primary light source *P* in object plane *G* (Fig. 75, item *a*): (1) Mount object on slide using a cover glass of proper thickness (if high dry objectives are to be used) and place the prepared slide *H*

in position on stage. (2) Adjust tube length to manufacturer's recommended figure. (3) Open J to maximum aperture and locate it centrally by means of pinion head Y, Fig. 73, using scale on diaphragm mount. (4) Open L to maximum aperture. (5) Illuminate *plane* surface of mirror O with parallel beam produced by M and adjust O until object appears illuminated when viewed from side. (6) By means of coarse-focus pinion head lower objective until it almost touches object. (7) Apply eyes to oculars and rack objective upward until it appears in focus. Sharpen focus, using fine adjustment. (8) Place a piece of tinted glass over ocular, partly close L and focus image of L by racking condenser up and down by means of pinion head U, Fig. 73. (9) Center image of L with respect to circular outline of field by means of O; open L until it just disappears from field of view. (10) Remove ocular and view image of J in back lens of objective, center this image by means of pinion head Y, Fig. 73. (11) Close J until two-thirds of the area of the back lens is illuminated. (12) Replace ocular and focus with fine adjustment.

To image light condenser M (Fig. 75, item b) in object plane, repeat steps 1 to 4 inclusive of preceding method, then illuminate O with convergent beam and adjust O to illuminate object. Continue with steps 6 and 7, then focus image of light source on piece of paper held in plane of J by moving M back and forth. Continue with steps 8 through 12. When back lens of objective is viewed, an image of the primary light source should be seen.

Adjustment for oblique illumination depends upon the number of images of the aperture diaphragm that are formed in the back lens of the objective when this diaphragm is reduced in aperture and displaced from its central position.

The first step is to obtain critical axial illumination, using either of the methods described. Remove ocular, observe image of aperture diaphragm in back lens of objective as diaphragm is gradually closed; displace diaphragm to extreme position (using pinion head Y, Fig. 73) and rotate diaphragm in mount through 180°. If one, and only one, image of the diaphragm is seen, the adjustments for oblique illumination are largely a matter of trial and error. The operator should be guided by the following prohibitions, optical in nature: The aperture diaphragm should not be closed so far that the outlines of structural details become thick lines or that contour halos appear. The aperture diaphragm should not be displaced from its central position by an amount more than sufficient to produce a slight shading of the image.

If more than one image of the aperture diaphragm is seen, the extra, fainter diffraction images, occurring in pairs, are symmetrically situated with respect to the bright central image. Each pair of diffraction images is associated with a repeated linear structure of the object, the structure being oriented at right angles to the line of centers of the diffraction images. The closer the spacing of the structure, the farther apart are the diffraction images; in some cases the diffraction images are seen only when diaphragm is displaced from its central position. Spacing of diffraction images is affected also by the wave length of light used, increasing as the wave length decreases. The principle followed in obtaining oblique illumination is to shift the aperture diaphragm from its central position until back lens of objective contains in addition to the central image as many of the diffraction images as possible (one member of each pair). The aperture diaphragm is then opened (viewing image with ocular in place) to maximum aperture possible without loss of resolution.

Adjustment for dark-field illumination. (1) Select a dark-field slide (special slides provided by manufacturers) free of scratches; clean thoroughly, dry, and free slide of all dust particles. (2) Make a wet mount of object and cover with a thin, clean cover glass; place slide on stage. (3) Adjust tube length to manufacturer's figure. (4) Open field and aperture diaphragms (L and J, Fig. 75). (5) Place objective into nosepiece; any objective with N.A. < 1.00 may be used; if an objective of higher N.A. is used, it must be equipped with an iris diaphragm which is closed to exclude all illuminating rays or with a funnel (accomplishing the same result) inserted over the back lens of the objective. Specially designed objectives are used when specially designed mounting equipment (such as quartz slide and cover glass of Bausch & Lomb Co.) is used. (6) Illuminate plane surface of mirror with light from source (preferably arc light) made parallel by moving light condenser. (7) Adjust mirror so that light falls perpendicularly on the under side of the stage condenser; this is done by observing a reflected disk of light which moves about near the *light* condenser as the mirror is tilted; adjustment is correct when this spot disappears into the center of the light condenser. (8) Place a drop of water or glycerine on the top lens of the stage condenser; raise condenser until liquid wets under side of slide. (9) Using a low-power objective, focus on object. (10) Raise or lower condenser until the smallest spot of light is secured. (11) If spot of light is off center, adjust centering screws of condenser until spot is concentric with field of view. (12) Swing higher-power objective into viewing position and focus with fine adjustment.

Troubles in use are many and varied; the following is a limited survey of those more common:

1. Indistinctness of image or loss of light is usually due to soiled or coated surfaces in ocular or objective; locate by rotating eyepiece (see p. 73). Clean optical parts as follows: (a) Blow surface clean, using rubber-bulb blower; (b) breathe upon surfaces and wipe dry with lens paper, using circular motion; (c) clean surface, using lens paper moistened with xylol; and (d) breathe on surface, wait for condensate to evaporate and blow surface clean.

2. Extreme brightness of image (to the point where eyes lose sensitivity) is due to intensity of illuminant. Intensity is decreased by the insertion of daylight-tint disks (polished on both sides) into aperture-diaphragm mount. Do not control light intensity by stopping down the aperture diaphragm.

3. Thin, barely visible outlines of structural details may be due to high intensity of illumination, use of excessively large opening in aperture diaphragm, or to the use of a mounting medium whose

refractive index closely approximates index of object. The first cause is removed as in (2); the second, by proper adjustment of aperture diaphragm; and the third, by preparing a new slide, using a different mounting medium.

4. Thick, broad outlines of details accompanied by general murkiness of field is probably due to low N.A. of condenser. If N.A. of condenser has been controlled by diaphragm, open until two-thirds of the area of the back lens of objective is illuminated; otherwise replace condenser with one of higher aperture (if top element of condenser had been removed, replace it).

5. Nonuniform illumination of image may be due to noncentering of condenser or aperture diaphragm; if image of primary light source was formed in the object plane, it may be due to lack of uniform radiation over the surface of the actinic element or to noncentering of light image in the field of view. Condenser and aperture diaphragm are centered as described on pages 88 and 77 respectively. Light image is centered by centering image of field diaphragm (see p. 77) and/or centering light source relative to field diaphragm (see p. 88). If difficulty is due to radiating element, change light source.

6. Flares in the image may be due to use of an eyepiece unsuited to the objective, or to air bubbles in the immersion medium. In the latter case the glare spots are roughly circular in shape and move when the slide is moved. Removal of defect is achieved by cleaning objective, slide, and condenser, followed by renewal of immersion liquid.

7. Dark band either concentric with field of view or off center therewith may be due to improper adjustment of field diaphragm. Center diaphragm (p. 77) and open until it clears field of view; if the latter is impossible, reduce aperture of condenser by removing top element, and if this is insufficient, remove condenser and use concave surface of mirror.

8. Lack of sharp definition to edge of field may be due to optical quality of ocular or to use of cover glass of incorrect thickness. If ocular is known to possess good definition, correct for cover glass thickness (see p. 74).

9. Opalescent appearance of dark-field image is due to lack of cleanliness or poor quality of slide and/or cover glass.

10. Dark-field image contains an annular ring of light which cannot be removed by racking condenser up and down; this is due to use of a slide too thick for dark-field work.

Metallurgical microscope is a compound microscope designed for examination of opaque objects, the image being formed of the reflected rays only. It is capable of magnifications ranging from 30× to 2,000×. Its particular field is in examination of reasonably plane surfaces.

Stand is essentially the same as Fig. 73, differences being absence of substage apparatus (item *b*), and provision of a rack and pinion for vertical movement of the stage.

Vertical illuminator (Fig. 76) screws onto the lower end of the body tube *G*, in the position normally occupied by the objective. It comprises: (*a*) A reflecting glass plate and a total-reflecting prism, both mounted on bar *A;* movement of *A* along its axis places one or the other of these reflectors in the optical system. (*b*) A field diaphragm adjusted by *B*. (*c*) A condensing lens adjusted by *C*. The lower end of the housing is equipped with an objective clutch *D*, to hold objectives provided with suitable adapter collars *E*.

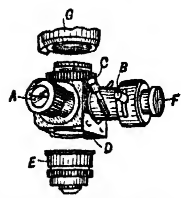

Fig. 76. Vertical illuminator (*Leitz*).

Objectives are special. They have short mounts to allow the reflecting surface of the illuminator to come as close as possible to the back lens of the objective, thus avoiding flare and loss of light; they are corrected for use without cover glass and are computed for a longer tube length, owing to interposition of the illuminator between ocular and objective (Bausch & Lomb, 215 mm.; Leitz, 215 mm.; Zeiss, 190 mm.). Achromatic, fluorite, and apochromatic types are available; numerical apertures range from 0.10 to 1.40. Objectives of N.A. > 1.00 are immersion types; they must be oiled to the object; others are used dry.

Oculars are same as those used with transmitted-type microscope (see p. 75).

Aperture diaphragm is located externally between light source and illuminator in such a position that it is imaged in the back lens of the objective.

Adjustment for axial illumination. (1) Place object on stage. (2) Adjust light source and light condenser so that rays enter window *F* of vertical illuminator (Fig. 76). (3) Open field and aperture diaphragm. (4) Adjust *A* so that glass plate is in reflecting position. (5) Focus on object by means of coarse-focus adjustment. (6) Close field diaphragm and focus an image thereof in plane of object by moving condenser handle *C* back and forth. (7) Center image of field diaphragm with respect to field of view by rotation of *A*. (8) Open field diaphragm until it just clears field of view. (9) Move light condenser until an image of its surface is formed in the object plane. This is best done by temporarily locating some opaque object at the surface of the light condenser, and moving condenser until an image of the object is formed in the object plane. (10) Remove ocular, view back lens of objective, and move light source until its image is formed in the back lens. (11) Close aperture diaphragm and move it along optical axis until an image of it is formed in the back lens of the objective. (12) Center aperture diaphragm by moving it in directions perpendicular to optical axis, then open diaphragm until two-thirds of the area of the back lens is illuminated. (If total reflecting prism is used, only a semicircular portion of the back lens is seen, and the aperture diaphragm is centered with respect to this semicircular field of view.) (13) Replace ocular and sharpen focus with fine adjustment. (14) Repeat steps 1 to 13 incl.

Adjustment for oblique illumination is obtained by first adjusting instrument to give critical axial illumination and then by proceeding as on p. 77

Troubles arise primarily from failure to obtain critical illumination. If field diaphragm is not open sufficiently, a sharp black outline appears about the field of view; if this diaphragm is improperly imaged in object plane, the outlines of this dark area are diffuse; if the diaphragm is decentered, the dark band intrudes on center of field of view. Lack of contrast in image may be due to excessive opening of field diaphragm. A decentered aperture diaphragm produces uneven illumination. If aperture diaphragm is too far open, thin, nearly invisible outlines result; if closed too far, thick outlines are produced accompanied by diffraction images. If image details and image of field diaphragm shift during focusing, the plane of the object is not perpendicular to the optical axis.

Dark-field vertical illuminator is used primarily when surface relief is to be resolved. It comprises: (*a*) An illuminating tube *A* (Fig. 77) containing two condensers so located that their principal foci coincide (or an illuminating tube *B* containing two condensers, and a light source placed at the principal focus of the lens combination). (*b*) A reflecting annular mirror *C* which receives a parallel beam of light from the illuminating tube and directs it into the condenser. (*c*) A ring condenser *D* carried by the objective holder *E*. (*d*) A slit *F* in the illumination tube for the insertion of diaphragms and/or filters in the path of the incoming light.

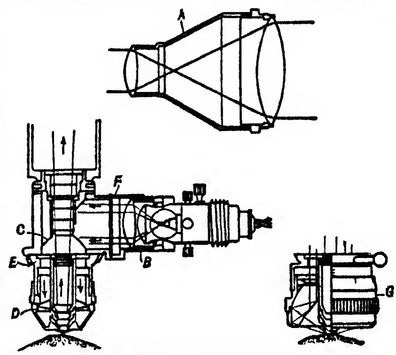

FIG. 77. Dark-field vertical illuminator (*Leitz Ultropak*).

Objectives available are: (*a*) Dry objectives, N.A. 0.12 to 0.65 and magnifications from 3.8 to 50×; (*b*) water-immersion objectives of N.A. from 0.55 to 1.0 and magnifications from 23× to 90×; and (*c*) oil-immersion objectives of N.A. from 0.25 to 1.0 and magnifications from 11× to 100×. These objectives are corrected for a tube length of 185-mm. and for use without a cover glass; the low-power and immersion objectives may be used with cover glasses without detriment to the image. The low-power (3.8× to 11×) objectives are each provided with a special ring condenser *G*, the high-power objectives (22× to 100×) are used in conjunction with a different ring condenser.

Oculars of Huygenian or periplanatic types (see p. 75) are used.

Adjustment of illumination. (1) Illuminate entrance condenser of illuminating tube with parallel light. (2) Remove all diaphragms or filters from slit, place a piece of white paper in object plane about 1 in. below illuminator housing (objective holder not in position). (3) Center light source (by movement at right angles to direction of rays) until the annular ring of light seen on paper is uniformly illuminated. (4) Place objective holder, together with objective and condenser, in position. (5) Adjust tube length to 185 mm. (6) Place object on stage and focus by moving stage toward or from objective (if portable light source is used coarse pinion head of body tube may be used for focusing). (7) Set ring condenser by rotation about mount to mean position recommended by manufacturer for the particular objective in use. (8) Displace ring condenser above and below mean position until field of view is evenly illuminated.

Depth of focus may be increased by the insertion of diaphragms (1.5- to 5-mm. openings) in the slit. Loss of definition accompanies the increase in depth of focus, hence judgment must be exercised.

Troubles in use, aside from those due to dirty optics, derive mainly from improper illumination. Uneven illumination of image may be due to decentralization of light source or improper location of ring condenser. Thin, barely visible image outlines may be due to high intensity of light source; remedy is to place a daylight filter in slit *F*. Thick image outlines may be due to use of a diaphragm with too small an opening.

Uses. The dependence of image illumination upon orientation of object planes (relative to the instrument axis) is the same as for transmitted work (see p. 75). Axial reflected illumination is used in the examination of polished sections of opaque materials, of opaque mineral fragments, process products (mounted or unmounted) such as concentrates, middlings, and tailings from flotation operations, etc. Oblique illumination is used primarily to increase contrast in the image of materials normally examined by axial illumination. Dark-field illumination is used in examination of pitted opaque surfaces, of slime-coated particles, of translucent minerals to produce internal reflections enabling identification, of transparent minerals to study inclusions, etc.

Mounting. Proper mounting and polishing of the specimen are important to image quality. If the specimen is unaltered by temperatures below 125° to 135° C., and by pressures below 3,000 to 4,000 lb. per sq. in., the usual procedure is to mount the specimen in either an opaque or transparent plastic. This mounting is done in machines especially designed (Buehler specimen-mount press).

The mold, 1- to 1 1/4-in. diameter, with seat in position, is charged with the specimen and with mounting powder, the ram is put into position, and the completed assembly, together with an electrically

heated jacket, is placed on the stage of a hydraulic press. The mold is heated to such a temperature and subjected to such pressure as is prescribed for the particular mounting powder used. Opaque plastic is usually red or black bakelite powder; an extra hard, translucent, amber-colored bakelite powder is also available; the transparent powder is LUCITE. If the specimen cannot withstand the pressures required by this method, as is the case with porous materials, place the sample in a suitable mold, such as a 1-in. round or square pill box, and cover with a sufficient amount of bakelite resinoid No. BR-0014. Cure at 75° C. for about 24 hr. or until the surface is gumlike and shows some resilience when dented with the finger. Next cure for 24 to 30 hours at 90° to 100° C., stopping while the blank, at oven temperature, can still be dented by the finger. Cool slowly to room temperature (Bird, *136 J 233*). Other methods of mounting are described by Head (*RI 2257; TP 10 UU; Bul 391 USBM 10*), Thomson (*8 Amer. Miner. 99; 19 CIMM 706, 1956*), Short (*21 Econ. Geol. 648*), and any of the standard texts on mineragraphy.

Specimen polishing has for its objects the attainment of a surface free of pits, scratches, undulations, and of relief between soft and hard minerals. The effect of pits and scratches is to distract attention, produce modifications of unknown amount in apparent color, hardness, and chemical behavior, and by removal of a component, to introduce an element of incompleteness and uncertainty in results. Undulations of the surface affect interpretation of the image by producing shadows and high lights of varying intensity. Relief puts hard and soft minerals in different planes, necessitating change of focus for examination; it also obscures the boundary between minerals, a site whose examination yields critical information in a large number of problems. Good specimen polishing has been most closely approached by abandoning use of the rolling abrasive for fixed abrasive. In fixed-abrasive methods (Vanderwill, *23 Econ. Geol. 292*) the abrasive is embedded in the surface of the lap, which is made of lead, lead-tin alloy, copper, or some other metal soft enough to hold the abrasive particles and still not yield under the action of the specimen. It is customary to have one such lap for each polishing stage, as this minimizes chances of getting particles of coarser abrasive into the lap in subsequent stages.

Specimen preparation consists in (*a*) cutting a specimen from a larger sample and shaping it, (*b*) grinding, to produce a flat, semipolished surface, and (*c*) polishing to produce a flat scratch-free mirrorlike surface. There are many manipulative difficulties. Successful technique involves cleanliness, care in handling the specimen, and patience. A particle of grit on the polishing lap may ruin an otherwise perfect specimen; rough contact with a hard surface, as by dropping, produces similar results; impatience during grinding usually results in coarse scratches which no amount of polishing will remove without introducing new defects.

Cutting and shaping are best done with a copper wheel rotated in a vertical plane at high speed, the lower segment of the wheel operating in a trough containing a pulp of commercial diamond dust or other suitable abrasive. The specimen may be hand hewn with chisel and anvil, but hewing may produce unseen cracks which appear in later stages. Dimensions of specimen vary, $1 \times 3/4 \times 3/4$ in. is usual. Final shaping may be done during coarse grinding.

Grinding is done with emery papers or with grinding laps. Grinding with papers usually starts with a paper of about 120 grit, and is followed by successively finer papers, Nos. 1, 0, 00, and 000. The paper is placed on a clean, flat, hard surface (plate glass) and the specimen gently drawn back and forth over the full length with moderate pressure. If the resulting slight curvature of the edges is objectionable, the specimen should be drawn across the paper in only one direction. In going from one paper to another, the specimen should be held in such position that the new, finer scratches are approximately at right angles to the old scratches; grinding on successive papers is continued each time until the previous scratches are completely removed.

Grinding laps are disks faced with a lead or 50–50 lead-tin alloy (*27 ASM 382*). The face of the lap has a spiral groove directed counter to the rotation. It is good practice to use a separate lap for each grinding stage, thus reducing carry-over of coarse abrasive from an earlier to a later grinding stage. Abrasives of increasing fineness, *i.e.*, Nos. 180, 303 1/2, and 305 emery, are used in successive stages. The specimen is moved continually from center to edge and the direction of grinding is changed in going from one lap to another. Grinding is continued on each lap until scratches from the preceding stage are removed.

Polishing, usually in two stages, is done on rotating, cloth-covered disks using fine powders. For preliminary polishing, a disk covered with a cloth of moderate nap (billiard-table covering, broadcloth, or light-weight canvas duck) and charged with a water suspension of No. 600 alundum powder is used. During polishing, the specimen is moved continuously back and forth from center to edge. Polishing is continued until previous scratches are removed. The suspended abrasive is best fed continuously from a shaker bottle; the lap should be neither too wet nor too dry, and here experience is the only teacher. For specimens that tend to pit or develop excessive relief, a cloth having no definite pile (silk, airplane wing-covering) should be used; or better still, preliminary polishing should be eliminated. Final polishing is done on a disk covered with a well-piled cloth (Forstmann's cloth, velveteen, etc.) using a suspension of alumina, magnesium oxide, rouge, or chromic oxide. During polishing, the specimen should be rotated counterwise to the rotation of the lap. Final polishing is considered finished when no scratches are visible on the surface at 100×. Attainment of this condition should not require more than 5 or 10 min. polishing.

Petrographic microscope (Fig. 78) is a compound microscope designed for examination of opaque or transparent objects with polarized light.

Stand is essentially the same as that of the research microscope (Fig. 73); the body tube *T* (Fig. 78) differs from the ordinary body tube in that it is slotted to receive various optical parts.

Stage S is circular, revolving-type, centered and edge-graduated in degrees, and provided with a locking clamp and vernier which enables settings to be read to 3′ of arc.

Optics (Figs. 78, 79) comprise: (*a*) MIRROR *A* (plane on one side, concave on reverse) mounted in usual substage position. (*b*) A centered APERTURE DIAPHRAGM *B*, located immediately below the polarizer *C*. (*c*) A Glan-Thompson PRISM, used to polarize incoming light, is mounted in rotatable fitting *C*, graduated in 10° intervals and capable of rotation through 360°; a detent is provided to locate zero position. (*d*) Interchangeable CONDENSERS *D*, item *b*, of N.A. 1.1 or 1.4, are mounted on beveled base plates which fit into groove of substage-condenser holder. Top lens of condenser is mounted on arm *E*; it may be swung out of position by means of knurled knob *F*, leaving a condenser of N.A. 0.28. Condenser is also equipped with an aperture diaphragm *G*, centered relative to condenser mount, and an adjustable shadow plate *H* (used in Becke line tests for refractive-index measurements). (*e*) OBJECTIVES of the achromatic and fluorite types (N.A. 0.1 to 1.3, magnifications 3× to 100×) screw into objective holder *I*, centerable by means of keys *J*. (*f*) An ANALYZER *K* of the Ahrens prism-type, mounted in a rotatable fitting graduated in 5° intervals and capable of 90° rotation, is located on a slide operating within the body tube. (*g*) Two stigmatizing LENSES *L* and *M* (Fig. 79) are mounted within the body tube; *L* produces a parallel beam of light through the analyzer, *M* converges rays emerging from the analyzer and focuses them in the plane of the field diaphragm of the ocular. (*h*) A Bertrand lens *N* together with an iris diaphragm *O* is mounted on a slide base (centerable by means of keys *P*) which operates in a groove located on a focusable sleeve *W* operating within the body tube. (*i*) Oculars *U* of Huygenian and flat-field type, equipped with cross hairs and so constructed that the top lens is carried by a cylindrical mount movable relative to the ocular mount, by which means the cross hairs are accurately focused. Notches in the upper edge of the eyepiece tube provide easy means for locating azimuth of eyepiece.

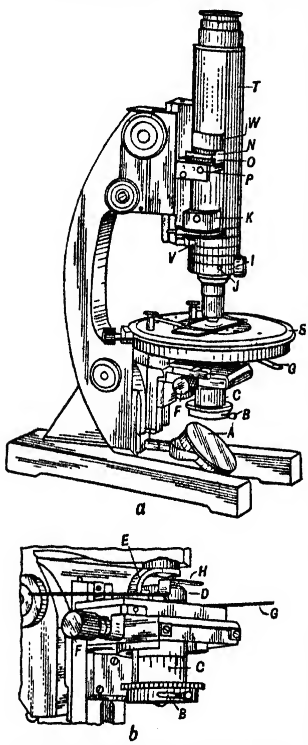

FIG. 78. Petrographic microscope (*Bausch & Lomb*).

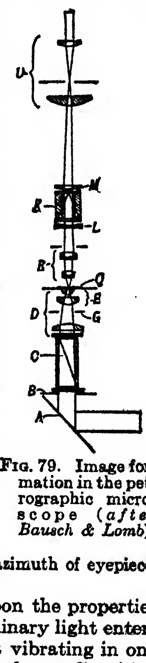

FIG. 79. Image formation in the petrographic microscope (*after Bausch & Lomb*).

Image formation in the petrographic microscope (Fig. 79) depends upon the properties of polarized light and the nature of its interaction with the object. Ordinary light entering polarizing prism *C* is converted into plane polarized light (*i.e.*, light vibrating in one direction only). The polarized beam thus produced passes through condenser *D*, which acts to focus light upon object *Q*. Light and object may interact in a number of ways depending upon the optical characteristics, thickness, and orientation of the object. In general, the beam refracted by the object is polarized in one or more directions (different from the direction of vibration of the incident light). Rays refracted by the object are taken by the objective *R*, which acts to form of them a primary enlarged image. The primary-image-forming rays are intercepted by the stigmatizing lens *L*, which redirects rays to form a parallel beam (necessary to keep optical defects due to passage through the analyzer at a minimum). This then passes through an analyzing prism *K* whose function it is to allow passage therethrough of only those rays (or components of rays) whose direction of vibration is parallel to some fixed direction (determined by the setting of the analyzer). The filtered beam then passes through a second stigmatizing lens *M*, which imparts to the rays the directions possessed before passing through the first stigmatizing lens. The beam then enters ocular *U*, which forms a secondary enlarged VIRTUAL (orthoscopic) IMAGE. The interaction of the convergent plane-polarized beam produced by the condenser and the object may give rise to interference phenomena which are imaged

in the back lens of the objective. These phenomena may be viewed by removing the ocular and examining the small image formed in the back lens, but they are more readily seen by interposition of the Bertrand lens N (Fig. 78) between ocular and objective; ocular and Bertrand lens then form a secondary microscope which is focused on the back lens of the objective. The diaphragm O provided with the Bertrand lens serves to exclude effects due to object areas other than the one of interest. The image thus formed is said to be CONOSCOPIC.

Adjustment for orthoscopic observation. (*a*) Place object slide on stage. (*b*) Illuminate mirror and adjust to direct beam into polarizer. (*c*) Displace Bertrand lens and analyzer out of optical system; open all diaphragms and swing top lens elements of condenser out of position, if low-power objective is used. (*d*) Focus on object. (*e*) Close field diaphragm and focus its image on object plane by racking condenser up and down. (*f*) Center field diaphragm image by means of mirror, then open diaphragm until it just clears the field of view. (*g*) Remove ocular and adjust lower aperture diaphragm B (upper diaphragm G is used with high-power objectives) until its image in the back lens of the objective covers two-thirds of the lens area. (*h*) Replace ocular, insert analyzer into optical path, and refocus with fine adjustment.

Adjustment for conoscopic observation. (*a*) Repeat steps *a* to *f* inclusive, as for orthoscopic observation, using a high-power objective. (*b*) Insert analyzer into optical path and set to crossed position, *i.e.*, to such a position that no light is transmitted by analyzer when object is out of the optical path. (*c*) Insert Bertrand lens and focus the interference figure now visible through the ocular by moving Bertrand-lens sleeve up or down. (*d*) Close Bertrand lens-diaphragm (if needed) to exclude extraneous figures.

Uses. Primary use is for the determination of optical characteristics of transparent natural and artificial minerals, resulting in identification of unknown materials. The literature of microscopic mineralogy and petrography (examination of thin sections and fragments) gives excellent detailed information concerning the microscopic determinations. A selected bibliography follows. The instrument is also used to reveal crystalline characteristics in materials which otherwise appear amorphous, and to expose the presence of crystals mounted in a medium of equal refractive index.

Example. Place a pinpoint of grease on a slide and cover with a cover glass; place another slide over cover glass and squeeze the two slides together until grease spreads out into an almost invisible thin film. Examine with biological microscope at 1,800×, using objective of 1.4 N.A. (amorphous appearance).. Transfer slide to petrographic microscope and adjust instrument for orthoscopic observation, using 45× objective (0.85 N.A.) and 10× ocular. Set analyzer and polarizer in crossed positions and rotate stage, when various parts of the field will appear bright while the rest is dark. These areas will change from light to dark on rotation of the stage. The weak birefringence exhibited by this material is more clearly shown by inserting a first order red plate in the slot V (Fig. 78) of the body tube, maintaining prisms in crossed position. As the stage is rotated, the material now shows brilliant color changes (evidence of crystalline matter).

Bibliography. F. E. Wright, *Methods of Petrographic-Microscopic Research*, Carnegie Institute of Washington; A. Johannsen, *Manual of Petrographic Methods*, McGraw-Hill Book Co.; E. M. Chamot and C. W. Mason, *Handbook of Chemical Microscopy*, 2 vols., John Wiley & Sons, 1930, 1931; F. G. Tickell, *Examination of Fragmented Rocks*, Stanford University Press, 1931; A. N. Winchell, *Elements of Optical Mineralogy*, 3 vols., John Wiley & Sons, 1929–1933; E. S. Larsen and H. Berman, *The Microscopic Determination of the Nonopaque Minerals*, U. S. Geol. Survey Bull. 848, 1934; Fry, *Petrographic Methods for Soil Laboratories*, U. S. Dept. Agr. Tech. Bull. 344, 1934; Head, *The Technique of Preparing Thin Sections of Rock*, University of Utah, 1929; Rogers and Kerr, *Optical Mineralogy*, McGraw-Hill Book Co., 1942.

Vertical illuminator (Fig. 76) with a polarizing prism, located at the window F, may be attached to a petrographic stand for use in the examination of opaque surfaces.

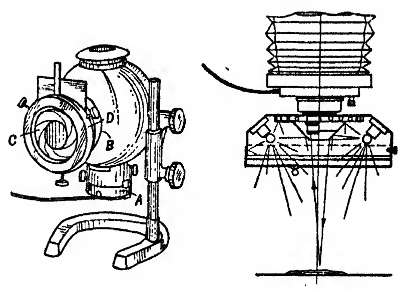
Adjustment for polarized reflected light. (*a*) Place object on stage. (*b*) Open aperture and field diaphragms, throw Bertrand lens and analyzer out of optical path. (*c*) Adjust illuminant so as to cast a beam of light into polarizer. (*d*) With plane-glass reflector in position, focus on object. (*e*) Close field diaphragm, focus by means of lens C (Fig. 76), center image by rotation of A, and open field diaphragm until it just clears field of view. (*f*) Remove ocular and close aperture diaphragm until two-thirds of the area of the back lens of the object is illuminated. (*g*) Replace ocular, insert analyzer into optical system, and adjust focus. (*h*) Rotate analyzer and determine position of extinction, turn analyzer to a position 2° to 4° away from extinction position.

Use in the identification of opaque minerals. The amount of information obtained from such examination is limited primarily to polarization colors and the existence of anisotropism. Recent improvements in equipment are rapidly overcoming this deficiency by making provision for measurement of the extent of elliptic polarization of the reflected beam. The literature of mineragraphy (study of opaque minerals) provides detailed information concerning techniques.

Selected bibliography. Farnum, *Determination of Ore Minerals*, McGraw-Hill Book Co., 1931; M. N. Short, *Microscopic Determination of the Ore Minerals*, U. S. Geol. Survey Bull. 914, 1940; E. S. Dana and W. W. Ford, *Textbook of Mineralogy*, John Wiley & Sons.

Illuminators for microscopic work are of arc or filament type. ARC LIGHT is characterized by a beam of high, though fluctuating, intensity, whereas the filament emits a beam of constant, though lower, intensity.

Filament-type illuminator (Fig. 80, item *a*) consists essentially of a light bulb mounted in a socket *A* at the base of a spherical housing, a condenser focusable in a sliding mount *B*, and an iris diaphragm *C*. Vents in the base of the socket and a chimney assure air circulation. Slot *D*, between diaphragm and condenser, is used to hold filters or diffusing disks. Bulbs with ribbon or coil filaments operated on 6-v. or 115-v. current are available. The lamp is mounted on a horseshoe-type base and should be adjusted vertically and/or inclined to any desired angle. Two types of CONDENSING SYSTEMS are available: a spherical system comprising two plano-convex lenses mounted together, or a more highly corrected system consisting of a single aspheric lens. Both systems are aided by a spherical reflector located within the housing.



a *b*
FIG. 80. Microscope illuminators.

Arc-type illuminator consists essentially of an arc light formed by two carbon electrodes held by clips to traveling blocks which operate in tracks (one vertical and the other horizontal) and are hand or mechanically actuated. The assembly enclosure has a sliding tube carrying a spherical or aspheric condenser with provision for focusing. Mounting is similar in principle to that in Fig. 80, item *a*, with an iris diaphragm and filter slot. The illuminator is designed to operate on 115-v., a.-c. or d.-c. The horizontal arc should burn to a crater (the vertical to cone) and the vertical should not be permitted to obscure the crater.

Water-cooling cells should always be used with either illuminator, since an uncooled light beam will eventually ruin the optics of the microscope. Such cells of rectangular form, made of Pyrex with polished plane surfaces (fused construction preferred) are available from any supply house. Water temperature should not exceed 50° C. since absorption of infrared rays at higher temperatures is practically negligible. For illuminators subject to long continuous use, cells equipped with inlet and outlet tubes providing continuous water circulation are available.

Ring illuminator (Fig. 80, item *b*) is designed for low-power photomicrography (see p. 89).

Testing with the Microscope

It is universal experience that understanding of natural phenomena always makes a tremendous advance whenever a structure, form, composition, motion, or the like, previously hidden from view, is made visible. The role of the microscope in ore dressing is to make such visibility possible in cases where inability to see otherwise is due to smallness of the hidden matter. Identification of mineral species, which, alone, many engineers associate with the use of the microscope, is probably its smallest and least important use in an ore-dressing laboratory. Determination of mineral association in the ore is important; determination of mineral association in milling products is more important; determination of mineral association in ore pulps, particularly while they are undergoing treatment, is most important. The microscope goes a long way in aiding these determinations. Techniques are reasonably well known and standardized for investigating ores and mill products—static conditions, as it were; methods for examining pulps, and for interpreting what is seen, are incompletely known and are far from standardized. They require a full knowledge of the optical apparatus available, ingenuity in its application, acuity of observation, patience, and perseverance.

The microscopes described will render the surface of almost any mineral fragment visible, and will give some information as to its internal make-up. Used with suitable nonoptical accessory tests they will give considerable indication of the chemical reactions of minerals with their surroundings. Used with ingenuity as to illuminating means, they will answer many questions as yet unanswered. Microscopy has, in the past, been left too largely to the microscopist without knowledge of ore-dressing technology; the space herein allotted to the subject is recognition that it is an essential tool for the mineral dresser.

Mineral association in an ore determines the method of beneficiation and the fineness of ultimate comminution necessary (see Sec. 5, Art. 1). When the valuable mineral is coarsely disseminated, sufficient information on this score can usually be obtained by a sizing-sorting-assay test, but finely disseminated ores cannot be studied intelligently

without a microscope. The procedure involves preparation and examination of thin sections for nonmetallic ores, and polished sections for ores containing opaque minerals such as the metalliferous sulphides and oxides. For methods of preparation, identification, and grain-size measurement, see *Bibliography*, pp. 82, 85. Grain-size determinations serve as a guide to the degree of grinding required to effect maximum liberation provided proper consideration is given to the mode of occurrence and relative hardness of ore minerals and gangue. For example, when an ore shows consistent ore-mineral deposition in fractures in the gangue, fine grinding is not necessarily indicated, for breakage will probably take place along these mineral-bearing fractures. The appearance of the edges of the sulphide-mineral grains and of cracks traversing them tells whether any alteration that would be likely to affect flotation has occurred. Inclusions of worthless or deleterious substances that would lower grade of concentrate, such as silicates between the laminae of graphite grains, blende in galena and the like, are immediately apparent in a polished section. The degree of admixture of sulphides in complex ores can be studied readily, and in many cases one or two properly chosen sections are sufficient to tell whether it is probable that separation can be effected without resort to chemical methods. Much time and money can thus be saved, and no test of any ore should proceed beyond the preliminary stage without such microscopic examination. If examination of a gold ore reveals the gold as minute metallic particles 1- to 3-μ diameter, completely encased in pyrite, it can be forecast that cyanidation of the ore ground to <325-m. would give a poor recovery; the best that would be hoped for is collection of the gold in a pyritic concentrate, followed by ultrafine grinding or roasting and cyanidation, or by smelting of the pyrite concentrate, the economics of the situation controlling the decision. With information such as the above, a good start can be made on a qualitative flowsheet.

Quantitative mineralogical analysis is useful primarily in study of the products of a concentrating operation. The first step is identification of the important minerals and mineral groups. The analytical work is done with low magnification, since identification of the valuable mineral, the accompanying heavy mineral or minerals, and rocky gangue minerals as a group is easy. Failing this, however, analysis must be preceded by identification, and for this work Rogers' crushed-fragment method with the petrographic microscope is best.

Apparatus. Low-power microscope, preferably binocular type, so mounted as to permit ready relative movement of stage and objectives. The stage should be ruled in squares about 10 mm. on a side and the microscope should have an eyepiece net micrometer with one of the squares subdivided. Leitz and Bausch & Lomb both make binocular microscopes for ore-dressing work having magnification up to 20×, fitted with racking mechanism in two directions at right angles, and provided with ruled stage and micrometer as above. For greater magnification a metallurgical binocular with 25- and 55-mm. objectives and 6× and 10× oculars is a suitable instrument; it is not usually fitted with racking stage, but the sample is mounted on a suitably ruled slide, when manual movement to change fields is readily effected.

Procedure consists in close, accurate sizing of the sample and a mineral count of a sufficient number of fields of each grade to establish a reliable number percentage. Sizing should be by the wet-dry method (Art. 12), grading fines by elutriation (Art. 13), if necessary. Coarser fractions can be transferred to and distributed on the slide by means of a small spatula. The layer should be only one grain deep and, if the grains are spaced at least one diameter, which may usually be accomplished by tapping the slide, counting will be made much easier. Finer grades are best transferred to the slide by shaking them on through a suitable fine screen. If, as is rarely the case, the analysis must be carried down into very fine water-separated grades, the methods of mounting employed in microscopic sizing analysis (Art. 15) should be used.

Sampling. Irrespective of the size of sample taken for screen analysis (see Arts. 1, 12), the bulk of most of the grades will be too great to permit mounting of the entire grade on one or even on several slides, and it is necessary to sample the individual grades. Sampling of such fractions for counting is one of the most difficult and unsatisfactory parts of the procedure. Probably the best method is to pour the lot through a small-necked funnel onto a glass plate, so as to form a cone-shaped heap, and then cone and quarter (Art. 2) with a small spatula, until a sample is obtained that will give the required layer one grain deep on the slide. A micro-riffle sampler (Art. 3) may be used. It can be purchased from any of the laboratory-supply houses.

Counting should proceed systematically. In the largest sizes, with a few particles only in each square, it is best to count all of the grains in the ruled field; in the intermediate sizes only the grains in selected squares need be counted, the squares selected being regularly spaced to cover the ruled field and the number counted being proportional to the size of grain, so that each size shall be analyzed with substantially the same degree of accuracy. Application of this criterion requires experience and judgment on the part of the analyst. The factors involved are: degree of uniformity of distribution of the different kinds of grains in the field, degree of uniformity in size of particles, amount of composite material (middling grains), relation of the weight of one particle to the weight of material in one square and in the whole field, relation of the weight of material in the field to the weight of the grade, and relation of the weight of the grade to the weight of original unsized sample. In the finest size the squares counted are the smallest in the micrometer net, and one or several of the squares in this net should be counted from each selected square on the stage net, according to the above criteria. Some

analysts recommend counting all or selected squares along one or both diagonals of the net, thus substantially cutting sections through the center of the field; others choose squares equally spaced in both directions covering the entire area. In no case should random selection or selection involving judgment on the part of the operator be permitted.

In counting the grains in any square it is best to carry through and record the count on each kind of grain separately. If one kind of grain breaks in such a fashion that its volume is consistently different from that of the grains of the other minerals in the grade, this fact should be noted and the relative volume established or approximated. In counting grains that are composites of the varieties sought to be separately reported, the relative volumes of the constituents must be estimated and if, as is usually the case, the relative proportions vary in different grains, the count should be classified on the basis of this proportion. Four classes are enough in any case, *viz.*, <25%, 25~50%, 50~75%, >75%. Grains containing traces of, say, sulphide should be classed as tailing and those containing traces of gangue as concentrate. For most purposes three or even two classes are sufficient.

The aspect of a grain presented to the eye in microscopic estimation is a surface aspect, whereas relative volume is the figure sought, hence the visual impression must be suitably weighted in recording the percentage estimate. Coghill and Bonardi (*TP 211 USBM*), analyzing a molybdenite flotation concentrate containing pyrite and silica, weighted FeS_2 and the MoS_2 locked in middling at two, compared to one for silica, basing the rating on the relative specific gravities, but the free MoS_2 was rated at one on account of its flaky character and the fact that the free flakes lay flat. Their microscopic analysis, thus weighted, showed 41.4% MoS_2 against 38.2% by chemical assay. Fig. 81 shows one of the fields counted, sketched by means of a camera lucida. This sketch, showing that most of the silica in this particular concentrate was in the form of middling, pointed the obvious conclusion that the proper method to raise the grade of concentrate was to grind finer.

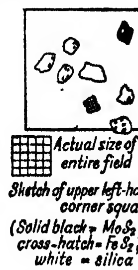


FIG. 81. Sketch of molybdenite flotation concentrate (*after Coghill and Bonardi*).

Time for a test will range from 3 to 8 hr. according to the size of sample and the number of minerals counted.

Photographic Testing

Use of photography to record microscopic images and other items of technical interest is associated with the adolescent period of photography; with its coming of age it has become available for use in a wide field of technology, particularly in the study of high-speed phenomena. In this aspect, the camera may be considered a magnifier of time as the microscope is a magnifier of distance. For example, action photographed on continuous film at the rate of 64,000 exposures (frames) per sec. and viewed at the normal rate of 16 frames per sec. will appear to have been slowed down by a factor of 4,000. Conversely, it may be used to speed up movement in slow change.

Essential elements of photography are: (1) the illuminating apparatus whose function it is to concentrate light of sufficient intensity on the object area to be photographed, (2) the photographic lens (or objective) which receives light from the object and focuses it as an image on the negative, (3) the photographic negative on whose surface the image is etched by photochemical reactions, and (4) a shutter (mechanical or optical) which controls the length of time (EXPOSURE) that the negative is subject to the action of the light.

Cameras are essentially light-tight boxes with lens and negative at opposite ends and, usually, a shutter between them. The distance between lens and negative should be adjustable, and the negative should be in a plane at right angles to the optical axis of the lens. Cameras are classified as fixed-negative or moving-negative types; fixed-negative cameras are further classified as hand or stand cameras depending upon the necessity for the support of a stand.

Cameras for an ore-dressing laboratory (research) should consist of two hand cameras (one taking a 35-mm. negative and the other a 4×5-in.), a stand camera (8×10-in. negative) mounted on an optical bench, a high-speed motion-picture camera, and a high-speed optical shutter (independent). The description of instruments and procedures that

follows is limited to basic uses; for information concerning accessories and advanced techniques, reference should be made to the technical literature and the catalogues and house organs of the manufacturers.

Manufacturers. Agfa Ansco, Argus Inc., Bausch & Lomb Co., Bell-Howell Co., A. Buehler, Candid Camera Corp., Cambridge Instrument Co., Central Camera Co., L. F. Deardorff & Sons, Duhem Motion Pictures Mfg. Co., Eastman Kodak Co., Folmer Graflex Co., Fearless Camera Co., General Engineering & Mfg. Co., Gundlach Mfg. Co., International Industries Inc., International Projector Corp., Keystone Mfg. Co., E. Leitz Inc., Mitchell Camera Corp., Paragon Camera Co., Rayflex Co., Revere Camera Co., Sharman Camera Works, Spencer Lens Co., Williams, Brown & Earle, Inc.; C. Zeiss.

Miniature camera is characterized by an extremely small negative size (24×36-mm.), compactness, and ease of handling. It comprises: (1) Lens *A* (Fig. 82) attached to the front of the body (which is 5 1/2×2 3/4×1 3/8 in.) by a mounting which is coupled to the range-finder and is focused by wheel *B*. (2) Sprocket wheels *C* to transport film from a full spool placed on claw *D* to an empty spool placed on claw *E;* a dial at *F*, actuated by *G*,

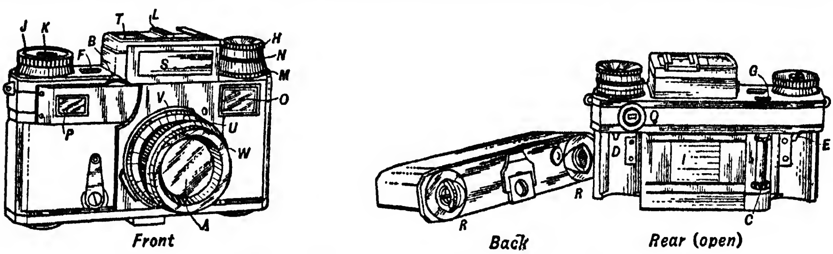

FIG. 82. Miniature camera (*Zeiss Contax*).

indicates exposures. Milled knob *H* rewinds film. (3) A metal focal-plane shutter *I*, coupled to the film transport mechanism so that winding of shutter automatically transports film, operates immediately in front of the film. Shutter is cocked by rotation of knob *J* and is set to the desired exposure time by lifting and rotating *J* until an index line thereon appears opposite this exposure time engraved on mount; release is made by pressing button *K* by finger or by bulb. (4) A photoelectric exposure meter *L*. Knob *M*, whose mount is engraved with shutter speeds, controls resistance used to balance the current generated by the photoelectric cell. Knob *N*, whose mount is engraved with all possible values of lens aperture, has a square cut out which moves over a scale of film speeds. (5) A combination range- and view-finder which determines distance of object to lens and shows field area has object windows *O* and *P* (which must be unobstructed during focusing) and an eyepiece *Q*.

Loading. (1) Remove camera back after giving locking keys *R* a half turn. (2) Engage full spool with claw *D*, with face (dull side) of film toward *I*. (3) Catch end of film in take-up spool. (4) Place this spool to engage claw *E*, and engage film perforations with sprockets *C*. (5) Replace back and lock by half-turns of *R*. (6) Press shutter-release button *K*. (7) Turn knob *J* to the right until it stops. (8) Press shutter-release button. (9) Turn picture-counter wheel *G* until it reads zero.

Exposure. (1) Set *N* to Scheiner speed rating of film (obtained from manufacturer). (2) Release cover *S* of exposure meter and point camera at darkest part of object to be photographed. (3) Rotate *M* until exposure-meter indicator comes to rest opposite diamond on scale *T;* close meter window. Read exposure time corresponding to any lens aperture on scale *M*. (4) Choose a combination of aperture and exposure that includes the maximum exposure consonant with the motion of the object and the method of supporting the camera. (5) Set diaphragm by turning *W* and exposure time by *J* (as above). Cock shutter, if necessary. Most operators recock shutter immediately after each exposure. (6) Hold camera firmly in the two hands, with the back lower corners against the bases of the thumbs, the crooked thumbs pressed against the camera back, the index fingers on top of *H* and *K*, the second finger of the right hand on *B*, and the other fingers of the two hands gripping the front of the camera in such a way as to clear windows *O* and *P*. (7) Look through eyepiece (camera gripped as in *6* and pressing against nose) and rotate focusing wheel with second finger of right hand until the dual image in the lighter, centrally located rectangle of the rectangular field of view fuses into a single image. The camera is now focused. (The distance in front and in back of the object within which all parts of the scene will appear in sharp focus, for a given aperture, may now be read from the depth-of-focus scale *V*. This information is useful in connection with *3* in performing *4*.) (8) Release shutter, when desired, by pressing *K* smoothly with ball of index finger. (9) Recock shutter.

Selection of exposure time (SHUTTER SPEED) depends upon the opening of the aperture diaphragm, the BRIGHTNESS of the object (amount of light reflected or refracted by object

under the prevailing conditions of illumination), the sensitivity of the film to light (FILM SPEED), the motion of the object, and upon the desired depth of focus. Object brightness is integrated by the exposure meter into a reading on dial *M*. Film speed is built into the film; its value in the integration is fixed by setting *N* when the film is loaded. The reading obtained on *M* fixes the exposure time to be used with a particular aperture, but does not fix either exposure time or aperture opening (denoted by *f*/ number, *e.g.*, *f*/1.5 to which it is related). If object motion imposes no limitations on exposure time, the desired depth of focus may be used to determine *f*-value and then shutter speed is read off scale *M* at the point opposite the chosen *f*-value on scale *N*. On the other hand, if the primary objective is to stop the motion of an object, the exposure time is estimated on the basis of object speed and distance from camera, and the necessary aperture setting is read from scale *N* opposite the estimated time. If stoppage of motion and depth of focus are equally important but lead to incompatible results, judgment must be exercised to effect a compromise.

Troubles in use chargeable to camera or film are remarkably few and arise from lack of experience. Failure to see the inner rectangle in the view-finder is due to obstruction of the window (usually by a finger). Inability to turn shutter winding knob immediately after loading is due to improper loading. Remove camera back, determine trouble, and correct. For negative failure see discussion on p. 90; for care of lens, p. 77.

Uses. The miniature camera is unexcelled for taking record pictures if demands for sharpness of enlarged prints are not too severe, *e.g.*, drill-core records requiring no enlargement are conveniently made with a miniature camera (*145 #5 J 86*). Standardization of set-up permits the recording of 100 ft. of hole in about 15 min. at a cost of about 25¢. ADVANTAGES are: the large number of exposures to the roll (36); the large aperture of the lens, which makes it possible to take picture under adverse lighting conditions; ease of focusing, small weight, and compactness; the chief DISADVANTAGE is the necessity for enlargement. It is used in the laboratory also for copying and for photomicrography; it is especially useful with a petrographic microscope because it takes Kodachrome film.

Hand camera (4×5-in. negatives) is shown in Fig. 83. Lens *A* and shutter *B* are mounted on a plate *C* held in position on a 4-in. square lens board *D* mounted on a track and moved by pinion heads *E* for focusing. Bellows *F*, 13 1/2-in. capacity, connects lens board to camera back, which is provided with a ground-glass focusing screen. A focal-plane shutter operates immediately in front of screen, and in conjunction with the lens shutter makes available 24 speeds ranging from 1 to 1/1,000 sec. A range-finder *G* coupled to the lens focusing device simultaneously determines object distance and focuses the camera. A view-finder *H*, adjusted to correct for parallax, depicts the field; for action shots a wire-frame finder *I* is used. Two types of backs are available, taking plates, cut film, film packs, and roll film. A revolving back permits the length of the negative to be placed vertically or horizontally without turning the camera. Principles of operation as a hand-held camera are as described for the miniature camera, but exposure meter is not built in. When ground-glass screen is used for focusing, operation follows that of the stand camera (see p. 88).

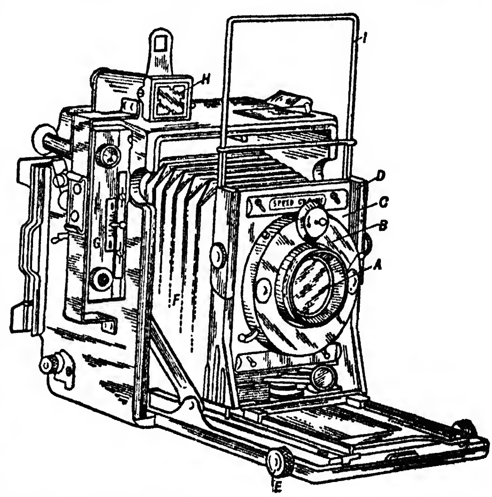

FIG. 83. Hand camera (*Speed Graphic, Folmer Graflex Co.*).

Uses. For outdoor record work when sharp prints are desired; for interior work, used with *f*/2.9 Plaubel lens and/or a synchronized flash; and as an all-purpose camera in the laboratory.

Stand camera (Fig. 84), mounted on an optical bench, is characterized by a large negative size (as large as 8×10-in.), lack of portability, by rigidity, and provision for elimination of vibration, all of which are of prime importance in photomicrography.

The camera consists of a tapering 40-in. extension bellows *A*, connected at the narrow end to a metal lens board *B* fitted with a shutter *D*, and at the wide end to an all-metal camera back *C*, grooved to receive book-type plate holders *E* (accommodating 8×10-,

5×7-, 4×5-, and $3\,{}^1/_4 \times 4\,{}^1/_4$-in. plates), or a ground-glass focusing screen (with clear center) or a clear-glass screen with graduated cross lines. The back and lens board are supported by a rectangular graduated bar *F*, hinged at *G* so that the camera may be used in vertical position. Extension rods *H* locate and stabilize *F* in the vertical position. Bed I, of the optical stand, carries pivot *G* of the camera support, a microscope plate support *J*, the illuminant *K*, and any other accessories that may be needed. The bed is supported by two rods *L* which pass through the table top into a support system equipped with vibration absorbers for use with time exposures. The microscope plate support *J*, capable of accommodating practically any microscope, is adjustable for height and

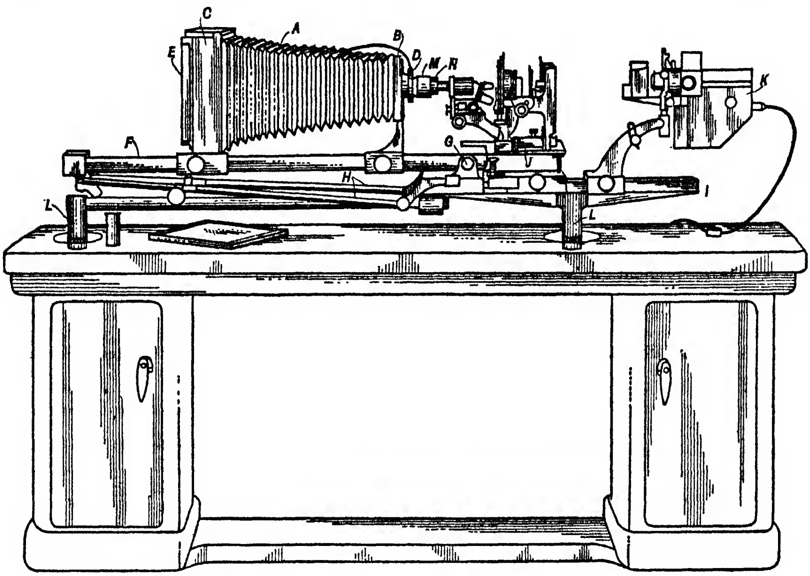

FIG. 84. Stand camera on optical bench (*Bausch & Lomb*).

provided with leveling screws. Clamps and guide plates are provided to hold the microscope in position on the plate. The illuminant is of the arc or filament type (p. 83); it may be adjusted in three directions and swung in a short arc in the plane of the bed.

High-power photomicrography using the optical bench and camera consists of three sets of operations. (1) Optical alignment, (2) focusing and taking the picture, and (3) processing and printing of negative.

Optical alignment requires that the optical axes of all optical parts of the set-up be collinear with an axis perpendicular to the surface of the negative and passing through its center. Alignment with the camera in a vertical position is more difficult than with a horizontal camera; the latter should, therefore, be used whenever possible. In the procedure for horizontal set-up that follows, it is assumed that all optics are located in centerable mounts; if this is not the case, centering has been done by the manufacturer.

Procedure. (1) Place ground glass in camera back and extend bellows completely. (2) Remove lens from lens board, screw light-tight connector *M* on shutter, set shutter to time, open, and close the iris diaphragm mounted on lens board (if none exists place a paper or metal disk, pierced with a pinpoint in the exact center, in the shutter mount). (3) Open field diaphragm (near lamp condenser), remove lamp condenser and adjust position of light until a light spot is seen in center of ground glass as determined by diagonals of back. If lamp condenser is not removable, center light with respect to condenser and then move light and condenser as a unit until the desired spot of light is seen. This places center of plate, center of diaphragm, and light on one and the same optical axis, the first two, which determine the optical axis of the camera, being fixed. (4) Replace light condenser and adjust it without moving anything else until light spot remains in center of ground glass when condenser is focused along the optical axis. (5) Clamp microscope on soleplate, remove ocular, objective, condenser, and mirror. Screw light-tight connector *N* onto ocular end of body tube, insert pinhole ocular cap (dummy ocular fitted with a metal disk with a pinhole perforation in the exact center). (6) Open diaphragm on lens board, bend microscope into horizontal position, and move lens board toward microscope until the light-tight sleeve connectors *M* and *N* intermesh. (7) Place aperture diaphragm (SUBSTAGE IRIS) in its central position relative to scale on mount and close to a very small opening. (8) Adjust microscope in soleplate or adjust soleplate until a small spot of light falls in the

of the ground glass. This aligns the optic axis of microscope, determined by center of ocular and center of aperture diaphragm, with axis already determined for the stand. (9) Move lens board of camera away from ocular, replace pinhole eyepiece with a regular ocular, place objective into viewing position, place condenser in substage mount; place object on stage, and rack condenser until it nearly touches object. (10) Focus light condenser until an image of the light source is formed on aperture diaphragm. A piece of white cardboard held against diaphragm facilitates viewing. (11) Open aperture diaphragm and focus microscope on object, using dark glass ocular cap, if image is too bright. (12) Partially close field diaphragm and rack condenser (substage) until image of field diaphragm is seen in field of view. (13) Center either objective or substage condenser (one or the other is centerable, and in rare cases both, when the stage may also be centerable) until this image is in center of field of view. (14) Open field diaphragm and repeat (10), then repeat (12), finally open field diaphragm until it just disappears from field of view. (15) Remove ocular, partially close aperture diaphragm, center its image in back lens of objective, if necessary, and then open aperture diaphragm until two-thirds of the area of the back lens of the objective is illuminated. (16) Replace ocular and check image quality. (17) Remove eyepiece and replace with a photo-eyepiece or a negative eyepiece (*e.g.*, Homal of Zeiss Co.). (18) Move lens board of camera until light-tight connectors form a light seal. (19) Focus microscope until image on ground glass is sharp. An extension focusing rod may be used if needed. Move camera back (*i.e.*, compress bellows) until image after refocusing is of proper dimensions. (20) Replace ground glass by clear-glass back and focus image as viewed through AUXILIARY MAGNIFIER (a two-lens magnifier previously adjusted so as to focus on the camera side of the glass back when it is held flush against the other side). (21) Replace clear-glass back with a loaded plate-holder, close shutter, remove plate-holder slide, and suspend optical bed. (22) When vibration ceases, open shutter (using cable release), expose for proper length of time, close shutter, lock optical bed, replace slide, and remove plate-holder to darkroom for developing and printing (*post*).

Low-power photomicrography using the optical bench and camera is simply a matter of focusing the camera and illuminating the object properly; the complicated procedures of alignment and critical illumination are unnecessary.

Illustrative procedure followed in photographing air-mineral aggregates formed in phosphate flotation follows: (1) Place sample in a Petri dish of medium depth; slowly add water and overflow an amount sufficient to leave clear water in dish. This is done to remove a surface film of oil and slimes which render the original solution cloudy. (2) Place dish on the matte surface of a piece of white bristol board on the soleplate. (3) Screw a photographic objective onto shutter on lens board; set shutter to time, open, open diaphragm of lens board (if present), open aperture diaphragm of lens, and raise camera to vertical position. (4) Fasten annular light ring to lens (see Fig. 80, item *b*), turn on light, and move lens board until image appears on ground glass. (5) Move camera back until image is of desired size. Move dish until image is located within the area to be occupied by negative (ground glass is ruled with outlines of the different negative sizes). (6) Measure distance between lens diaphragm and mid-depth point of object; measure or estimate depth of object. Calculate aperture diaphragm setting to give the required depth of focus (near distance $= Ll/(L + l)$, far distance $= Ll/(L - l)$, where $L = F^2/12fD$ and l = object distance in feet, F = focal length in inches, f = lens aperture f/number, D = diameter in inches of the largest circle that will appear as a point in the final print). (7) Focus critically upon the mid-depth plane of object. Set aperture diaphragm to calculated stop (a larger stop may be used if no objectionable background material exists). (8) Place loaded plate-holder in position, close shutter, remove plate-sheath, wait for all vibration to cease, expose plate for required time, replace sheath, and remove plate-holder.

Motion-picture cameras, characterized by use of a film moving behind a synchronized, intermittently operated shutter (rotating sector disk), are available in hand or motor-driven types capable of making 300 to 400 exposures per sec. High-speed motion-picture cameras making as high as 64,000 exposures per sec. on 35-, 16-, 8-, and 4-mm. film have been constructed (*11 Zeit. für tech. Physik 394; 4 J. Sci. Instr. 82; 17 Bell System Tech. Jour. 393; 25 Trans. Soc. Motion Pict. Engs. 25; 16 Electrical Jour. 509; 42 Gen. El. Rev. 391; 4 Rep. Aero. Res. Inst., Tokyo Imp. Un. 187; J. Soc. Motion Pict. Engs. 474*). Because of the high film velocities involved (4,000 f.p.s. for 35-mm. frame at 64,000 exposures per sec.) the design of these cameras is different.

Fastax variable high-speed motion-picture camera, designed by the Bell Laboratories (*22 No. 1 Bell Lab. Record 1*), is a compact, portable, motor-driven stand-type unit, capable of 300 to 8,000 exposures per sec. for 8-mm. film and 150 to 4,000 exposures per sec. for 16-mm. film. Image-forming rays from the photographic objective *A* (Fig. 85), mounted on a cylindrical housing, fall upon a prism *B*, with 4 faces for 8-mm. and 8 faces for 16-mm. film, rotated by gear connection to the film-driving sprocket *C*, and are refracted and emerge and come to a focus as shown on the moving film *D*. Film with twice usual number of perforations is fed over sprocket *C* by a 1/5-hp., universal, high-torque type motor, identical with the first, independently connected, but started by the same switch.

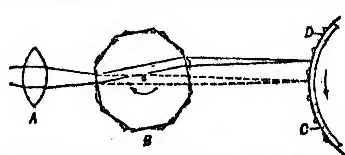

FIG. 85. Optical system of Fastax camera (*after Smith*).

Motors operate at 12,000 r.p.m. under full line voltage; variable resistors decrease r.p.m. so that exposures as low as 300 per sec. may be made (see Fig. 86). Since no clutch arrangement is used, film accelerates to about 90% of its maximum speed within the first 30 or 35 ft. exposed; full speed is not attained until toward the end of a 100-ft. roll; exposure through the last 65 to 70 ft. is approximately 1/30,000 sec. for 8-mm. and 1/12,000 sec. for 16-mm.

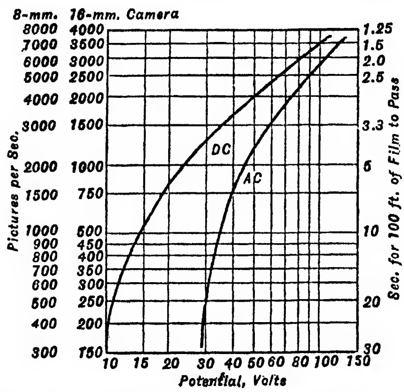

Fig. 86. Number of exposures *vs.* voltage (*after Smith*).

Lens is of standard design; used at stops $f/4.5$ to $f/20$. Camera is focused on a ground-glass screen before introduction of film.

Lighting is the key to successful high-speed photography. Illuminant must be capable of providing intensities at the object of 10,000 to 500,000 foot-candles. Projection-type tungsten-filament lamps, mounted in reflectors, provided with aspheric collecting lenses, are used; current is so controlled that filaments are heated to within a few degrees of their melting point, to secure maximum brightness. Water cells are interposed between light and object. In use, two lamps are wired in series during the set-up period and are switched to a parallel circuit immediately before exposure.

Uses. Study and analysis of mechanical movements, strength of materials tests, action of jig beds, table beds, flotation froths, etc.

Photographic materials consist of a thin light-sensitive layer (photographic EMULSION) of silver halide crystals suspended in gelatin, carried on glass, cellulose nitrate or acetate, or paper, respectively known as PLATES, FILM, and PAPER.

Plates and films are classified as ORDINARY when sensitive only to blue and ultraviolet light, CHROMATIC when sensitive also to green but not to red, and PANCHROMATIC when sensitive to all colors of the visible spectrum. Ordinary emulsions are used for copying black-and-white originals, etc.; orthochromatics for photographing objects containing no red, or when red details are unimportant; panchromatics for objects containing all colors. Each class is supplied in a number of grades developing different degrees of contrast.

Photomicrographic plates (film rarely used) suggested are: Wratten M (Eastman Kodak); panchromatic, fairly slow, fine-grain, fairly contrasty. Wratten Panchromatic; panchromatic, about 40% faster than M, coarser grain, and less contrasty. Eastman Commercial; orthochromatic, slow, fine-grain, medium contrast. Hammer Slow (Hammer Dry Plate Co.); ordinary, fine-grain, slow, very contrasty.

Processing negatives consists in DEVELOPING, *i. e.*, reducing the light-exposed silver halide grains to silver, in a solution composed and used in accord with manufacturer's directions; FIXING by dissolving the unexposed and, therefore, unreduced silver halide grains; WASHING to remove soluble chemicals from gelatin; and DRYING. Time in and temperature of the developing solution, and the amount of agitation therein are the important variables in development. Much experience is necessary for good work, but passable proficiency is readily attained.

Papers are GLOSSY, SEMI-MATTE, and MATTE, according to smoothness and reflectivity of the surface; each type is available in four or five grades of contrast. Glossy papers are used almost exclusively for technical prints, since sharpness of detail is the desideratum.

Printing and processing of papers proceeds as follows: (1) Place negative with emulsion side up on a printer consisting of a rectangular box containing two or three lights and having a frosted-glass top underlain directly by a red-glass slide; place a paper, emulsion side down, on the negative, with a weight to keep the paper flat. (2) Expose paper by withdrawing red slide; time of exposure is determined by trial. (3) Develop, fix, and wash in water in accord with directions supplied with paper. (4) Place washed print, emulsion side down, on surface of a waxed and polished, enameled or chrome-plated steel sheet (FERROTYPE), squeeze out all excess water with a rubber roller, and allow to dry.

Bibliography. Recognition, source, and remedy of troubles connected with processing photographic materials, as well as numerous techniques, are thoroughly discussed in the following texts: Henney and Dudley, *Handbook of Photography*, Whittlesey House, McGraw-Hill Book Co., 1939; Neblette, *Photography, Principles and Practice*, D. Van Nostrand Co., 1938. Troubles arising from improper adjustment of the microscope have been discussed (p. 77). (See also, Allen, *Photomicrography*, D. Van Nostrand Co., 1941; Barnard and Welch, *Photomicrography*, Longmans, Green & Co., 1936; and C. P. Shillaber, *Photomicrography in Theory and Practice*, John Wiley & Sons, 1944.

Filters are transparent colored bodies of glass, gelatin, or solution that transmit almost exclusively light of a particular color. Interpretation of the black-and-white print of a colored object requires rendition of the various colors in some intermediate half-tone which conveys an impression similar to the colors of the object itself. Filters are used to produce the necessary half-tones, *e.g.*, a red object area adjacent to a white object area, when photographed, may appear too dark in the print, but when a red filter is used the relative brightness of these areas in the print is decreased (contrast decreased) since now only the red portion of the white light enters the lens system and affects the negative. The principle to be followed in selection of filters is to use a filter of approximately the same color as the object when a decrease in contrast is desired, and to use a filter of the complementary color to increase contrast.

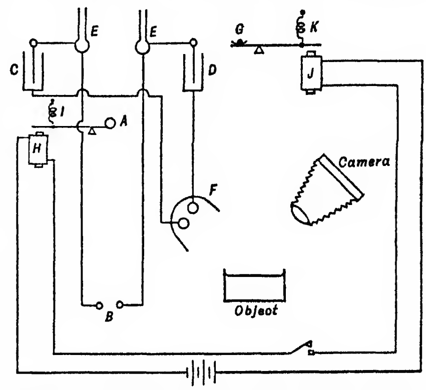

FIG. 87. Arrangement for photographing splashes (*after Worthington*).

High-speed photography is characterized by extremely short exposure times (10^{-4} to 10^{-7} sec.) and by the absence of mechanical shutters, shutter action being obtained by producing a light flash of short duration. Techniques and equipment vary depending upon whether the negative material is stationary or in motion.

The light source is a flash of light produced by the discharge of an electrical condenser through a gas-filled tube or gap. The condenser, connected to the electrodes, is charged just below the discharge potential of the gap; flashover takes place either by a sudden increase of potential in the condenser circuit, or by a dielectric breakdown in the gap. In Fig. 87, when ball A closes gap B, the condensers, comprising two Leyden jars, C and D, charged by terminals E of a Wimhurst machine, become series-connected, the potential across gap F doubles, and discharge takes place. In Fig. 88, an auxiliary circuit (TRIP

FIG. 88. Silhouette photography using spark and trip circuit (*after Edgerton, Germeshausen, and Grier*).

CIRCUIT) controls the instant of flash by applying a high potential at the desired time to a third electrode placed near the main gap; the spark from it to either or both of the main electrodes results in a dielectric breakdown of the main gap, which is immediately followed by discharge of condenser C_1. The intensity of the illumination depends upon the charging voltage and capacity of the condenser, the dimensions of the gap, and the nature of the electrodes; the duration depends upon the inductance of the discharge circuit, the resistance, the dimensions of the gap, and nature of the electrodes. Arc-type

sources using metal electrodes (magnesium, iron, copper, platinum, etc.), mercury-arc tubes, and gas-filled (argon, neon) tubes have been used. Magnesium arc gives a brilliant light flash of $<3\times10^{-6}$ sec. duration (Worthington, *A Study of Splashes*, Longmans, Green & Co., Ltd.), copper and platinum a less intense flash of about 10^{-7} sec. duration (Boys, *47 Nature 415, 440*), mercury-arc tubes (according to temperature of discharge) 10^{-5} to 10^{-6} sec. flash (Edgerton and Bermehausen, *3 Rev. Sci. Instr. 535*), and the gas-filled tubes a flash lasting about 10^{-5} sec., and of sufficient intensity to photograph a 6-sq. ft. area, using an $f/8$ stop on orthochromatic film.

Timing of the instant of flash may be accomplished in a variety of ways. In Fig. 87 ball A is released through the action of the magnet H and spring I simultaneously with release of liquid drop G through coaction of magnet J and spring K. By varying the height of ball A above gap B, the time of flash may be controlled to within 2×10^{-3} sec. The trip circuit of Fig. 88 may be energized either by mechanical or electrical closure of switch S_1 or by current input at S_2. For example, switch S_1 may be two wires that are knocked together by the object being photographed; this method was used by Edgerton in photographing a golf club hitting a ball. The flash was timed to within 10^{-4} sec. (See also Edgerton *et al.*, *22 ACerS 302*). Interruption by the object of a beam of light to a photoelectric cell or the impact of a sound wave, generated by the object, upon a piezoelectrical crystal microphone has been used to activate switch S_2 (Edgerton *et al.*, *8 J. App. Phys. 2*). The small photoelectric or piezoelectric current is put through an amplifying circuit, whose output terminals are connected to S_2. In either case, closure of a switch charges the grid of the Thyratron tube V_3, thus allowing condenser C_3 to discharge its energy into the primary of a step-up transformer T_3. The high voltage from the secondary is applied to the third electrode, which causes the dielectric break-down. In studying fracturing of glass, Edgerton *et al.* (*24 ACerS 131*) used an electric circuit which delayed the instant of flash by a known interval of time after the switch was thrown; in this way fracture progress was followed.

Camera used may be any of the fixed-plate types; because of portability and larger negative size the Speed Graphic is most advantageous. Since the camera shutter is open for some time before and after the flash, work must be done in a darkened room to prevent fogging of the plate. Arrangement of equipment and photographic procedure are simple (*10 Rev. Sci. Instr. 378, 11 ibid. 184; 9 J. App. Phys. 362; NACA Report No. 429*). The camera is focused on the object or on a point in space that will be occupied by the object at the time of exposure. The lens is stopped down sufficiently to give the desired depth of focus. Light source and camera are arranged as in Fig. 87 for photography by reflected light and as in Fig. 88 for transmitted light or silhouette photography. In the latter case the collecting lens should be so located as to completely fill the ground glass of the camera; alignment of camera, lens, and light may be accomplished by following procedure on p. 88. When all adjustments have been made, the room is darkened, the tab of the plate-holder in position is removed, the camera shutter is set for time, opened, and the switch is thrown.

Stroboscopic illumination is obtained by using an oscillating trip circuit (Fig. 89). A neon-filled tube (Strobotron) is so arranged in the circuit that conduction through

Fig. 89. Adjustable-frequency stroboscopic illuminator (*after Germeshausen and Edgerton*).

the tube cannot take place until the potential difference between the grids exceeds the starting potential of the tube; at such time condenser C_2 is discharged through the tube. The necessary potential difference between the grids is obtained by periodically impressing

a negative potential on grid G by means of the oscillator circuit. The oscillator may be operated within two frequency ranges by changing the circuit constants of the grid circuits of the oscillator, variation within each range being obtained by varying resistance R. With $C_4 = 0.02\mu f$, frequency range is 10 to 60 cycles per sec., when $C_4 = 0.005\mu f$, 40 to 240 cycles. The intensity of the illumination is not very high, hence when more intense lighting is required this circuit may be used to trigger a more intense illuminant. General Radio Co. manufactures stroboscopic equipment such as described.

Multiple-exposure photography, made possible by the use of a stroboscopic illuminator, requires a dark background on which is disposed a brightly illuminated object. If the object whose motion is to be studied is a good reflector of light, all that is required is to place the object M (Fig. 90, item a) in front of a black background and arrange light I and camera C as shown, with a scale S in the plane of the object. If the object is transparent and anisotropic, and requires illumination by transmitted light, a dark background may be obtained by placing two polaroid disks P (item b) in crossed position; only light passing through the object will reach the camera lens. In both methods it is advisable to work in a dimly lighted room, using a fixed-negative camera (miniature, or Speed Graphic), with shutter set at time.

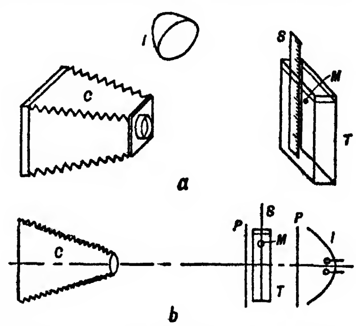

FIG. 90. Arrangement for multi-exposure photography.

Both arrangements have been used successfully (CU) to study free-settling characteristics of particles in liquids. Cell T should have parallel faces. Illuminator I should be arranged so that no reflections appear in the ground glass of the camera when focusing on the scale S. A mirror placed in front of the cell intensifies reflections. When ready to expose, dim the room, start the stroboscope, open shutter, set at time, and release the particle M; when the particle has reached the bottom of cell, close shutter.

Interpretation of the print requires determination of the distance between images as obtained from the scale included in the field of view, and of the time elapsed between images as obtained from the known frequency of the light flashes. The images corresponding to the acceleration period of the falling particle overlap, hence interpretation is difficult. However, if the camera is mounted on a tripod equipped with a rotating head, movement of the camera through a small arc will spread the images of the acceleration period. The camera axis must be perpendicular to the plane of object motion.

High-speed motion-picture photographs may be taken using a continuous light source (see p. 89) or an interrupted (stroboscopic) illuminator; in the latter case timing of the flashes may be achieved by the use of a contactor mounted on the sprocket shaft of the camera or by the use of an oscillator trip circuit. When the oscillator is used to control frequency of light, the time interval between light flashes must be equal to the time interval between successive frames on the moving negative. If the camera does not accelerate rapidly to some constant speed, overlap between successive frames at the beginning of the reel will take place. Edgerton (*54 EE 149*), using the contactor method, mounted the commutator on the shaft of the sprocket outside the camera body, and used stranded copper brushes, pressed against the commutator by springs, to eliminate vibrations and bouncing, which produce improper spacing of the frames. The camera was otherwise a normal high-speed camera, capable of taking 1,200 @ 35-mm. pictures per sec. A time record was made at the side of the film by a spark whose frequency was controlled by a 60-cycle oscillator.

Fluorescence of minerals resulting from excitation with ultraviolet light is used as an aid in mineral identification both in the laboratory and in the mill. Fluorescence depends upon the atomic structure of the mineral and the wave length of the radiation; it results from an absorption of the invisible incident radiation followed by conversion and re-emission as visible light of a particular wave length (color). Some minerals fluoresce when excited by radiation in the short end of the ultraviolet region but not with radiation from the long end and *vice versa;* some minerals undergo a fluorescent color change when excited by radiation from the two ends of the range, *e.g.*, Bohemian apatite gives white fluorescent light for short rays and brown for the long rays. Mineral identification in the mill is effective only with strongly fluorescent materials, since the mill is normally well lighted. Iron or mercury arcs equipped with filters transmitting in the ultraviolet range mounted over a picking belt or a concentrator may be used to identify the following minerals: Anglesite (yellow), apatite (white, yellow or brown, depending on locality and wave length), cerussite (pale blue or yellow according to locality), dolomite

(white or blue-white depending on locality and wave length), aragonite (white, pink, red, or green), calcite (pink to bright scarlet red, depending on Mn content), fluorite (blue), gypsum (green), scheelite (blue), sphalerite (orange), willemite (green depending on Mn content). For a more detailed listing, including weakly fluorescent minerals, see H. Dake and J. de Ment, *Fluorescent Light and Its Applications*, Chemical Publishing Co., 1941. See also Sec. 14, Art. 3.

10. CHEMICAL AND ELECTRICAL TESTING

Chemical testing of the nature of a material comprises primarily assaying, and qualitative chemical tests, both macroscopic and microscopic. These are specialized arts covering which there is an excellent literature. A brief bibliography follows:

Assaying

1. *Fire Assaying*, Shepard and Dietrich; McGraw-Hill Book Co., 1940.
2. *Textbook of Fire Assaying*, Bugbee, John Wiley & Sons, 1940.
3. *Manual of Fire Assaying*, Fulton and Sharwood, McGraw-Hill Book Co., 1929.
4. *Technical Methods of Ore Analysis*, Low, Weinig and Schoder, John Wiley & Sons, 1939.
5. *Select Methods of Metallurgical Analysis*, Naish and Clennell, John Wiley & Sons, 1930.

Radioactive tracer atoms have been used for a considerable variety of chemical and physical researches, *e.g.*, determination of surface area, diffusion in minerals (*7 ZP 13*), crystal habit and growth (*Hahn; Paneth*), co-precipitation, adsorption, electrochemical exchange, etc. Its applicability is limited only by the imagination of the investigator. It is particularly suited to any problem in which minute quantities are involved. The method depends upon the fact that radioactive elements, either natural (radium, thorium, etc.) or artificial (S, C, P, etc.) disintegrate spontaneously with emission of α (doubly charged helium ions), β (electrons), and γ (X-ray) radiation, and that such radiation can be measured with extreme accuracy. It is independent of any physical or chemical condition or the age of the substance; it is mathematically described by $N = N_0e^{-ft}$ where N = number of atoms at time t, N_0 = number of atoms at reference time $t = 0$, and f (disintegration constant) = fraction of the total number of atoms disintegrating in unit time, obtainable from published tables.

Detection of radioactive atoms is accomplished by utilizing the effect of the emitted radiations in making an air gap conductive and so discharging a gold-leaf electroscope or the like. Rate of discharge of the electroscope depends upon the number of disintegrating atoms fN; when f is known, discharge rate measures the weight of radioactive element. The method is readily sensitive to 10^{-12} gm. of thorium C, and 10^{-17} gm. may be determined (*Hahn*).

Basis of method is the fact that the radioactive atom possesses identical chemical properties with the inactive atom. Hence if thorium B, the radioactive lead isotope, is mixed with a known weight, say 0.01 gm., of inactive lead and the activity of the resulting mixture is determined to be, say, 1,000,000 units, each unit of thorium B represents 10^{-8} gm. of lead.

Experimental method depends upon the problem; in all applications electroscopic determination of active atoms is substituted for chemical determination of inactive atoms.

Solubility of lead chromate (*82 Z anorg C 322; 89 ZPC 294, 303*) was determined by preparing pure lead chromate by the usual chemical methods from a mixture of lead and thorium B, and subjecting the salt to the normal gravimetric solubility method. A known volume of the saturated solution was evaporated and the activity of the residue was determined. The units of activity multiplied by the ratio of inactive to active lead and divided by the volume of solution evaporated gives grams of lead dissolved per unit volume of solvent.

Flotation collection (*CU*). Two lots of lead ethyl xanthate were prepared, one using thorium B (Pb^R) and one radioactive S (S^R). A sample of <200-m. galena was shaken with the filtrate from a suspension of $PbEtX_2^R$ for 15 min., filtered, and the activity of the filtrate determined; it was found

that no EtX^R ions remained therein. A similar test, using Pb^RX_2 showed no loss of activity of the filtrate. The conclusion is that xanthate ions reacted with the galena surface; not that molecular lead xanthate adsorbed thereon.

Electrical tests supply information as to magnetic permeability and electrical conductivity. Neither piece of information is of any great utility, however, so far as identification of the mineral is concerned, except perhaps in so far as high susceptibility is a simple test for magnetite. The significant utilities of electrical tests are in process testing (Art. 22).

11. RESISTANCE TO COMMINUTION

The resistance of a rock to comminution is of major importance both as respects coarse and fine reduction (see Secs. 4, 5, 6). Much work has been done in the attempt to quantify such resistance.

Crushing. So far as crushing is concerned, all useful work to date boils down to determination of crushing resistance as compared with that of medium limestone, tests being made, if at all, by compression in an ordinary materials-testing machine. The more usual procedure is to determine the lithological class of the material and then refer to some comparative tabulation such as Table 3, Sec. 4. Laboratory crushing tests that are to be used as a basis of mill installation are about 5% manipulation and 95% interpretation based on experience, in any case, and an experienced investigator, with a few lumps of the unknown and some known rocks and a hammer and anvil, can tell more than an inexperienced man with a most complete laboratory crushing equipment.

Grindability is defined broadly as the resistance of a material to fine comminution. Experience has taught, however, that determinations of such resistance, whether expressed in absolute or relative units, are to be used with caution; that translation from laboratory to mill must, in fact, be limited to mills of the same type as those in which the tests were performed, grinding to the same *mog*, and under the same moisture conditions, and that even then it is wise to allow a generous factor of safety, and is much more comfortable to have a reasonably comparable plant performance as a check.

On the other hand, the establishment of a scientific basis for a measure of grindability and a method for its determination would make it possible, with suitable performance data, to select grinding equipment accurately, and to prescribe the proper degree and character of grinding for optimum metallurgical results.

Unit of grindability should be based on a valid law of crushing. Many so-called laws have been proposed (*98 J 905, 945*), the most popular being those of Rittinger and of Kick (*Ed. 1, 489*). Rittinger proposed that *the energy required for crushing is directly proportional to the increase of the surfaces exposed,* whereas Kick postulated that *the energy required for producing analogous changes of configuration in geometrically similar bodies of equal technological state varies as the volumes or weights of these bodies.* The work of Gross and Zimmerley (*87 A 7, 27, 35*) appears to have confirmed Rittinger's law, hence the grindability G is taken by them as the constant in Rittinger's law, or

$$G = A_S/E \tag{37}$$

where A_S = new surface produced, and E = energy consumed in its production; in c.g.s. units G is expressed in terms of sq. cm. per erg. The magnitude of G depends upon the elastic constants and the ultimate strength of the material; these depend, in turn, upon the magnitude, direction, point, and rate of application of the force or forces producing breakage.

Measurement of grindability, if direct, is predicated upon an ability to determine the surfaces of crushed materials and the energy consumed in crushing alone; if indirect, upon some measurable related property. There is no method for measuring the absolute surface of a powder; even the so-called direct methods (Art. 17) measure only properties related to surface. Measurement of energy actually consumed in comminution is more nearly successful, although there is room for improvement (*vide infra*). Thus determination of absolute grindabilities is, at present, impossible. There is some evidence that in some methods of measurement, true surface area bears a constant relation to the measured surface area; *i.e.*, the ratio of true surface areas approximates closely the measured ratio. If this be true, the ratio of measured grindabilities (relative grindability) closely approximates the ratio of true grindabilities. Many investigators make no attempt to measure true energy of crushing, but content themselves with the measurement of some related energy in the hope that the two stand in constant relation, *e.g.*, the energy input to a ball mill has been assumed to bear a constant ratio to the energy consumed in grinding because standardization of grinding conditions was practiced. See also *Bul 402 USBM.*

Drop-weight method (*87 A 7*) consists in crushing a sample in a drop-weight machine, calculating the energy consumed in crushing, and determining the new surface produced by a dissolution method. The machine comprises a steel mortar *m* (Fig. 91), 3 in. diameter by 3 in. high, with a crushing chamber *c*, 1 in. diameter by 1/2 in. deep (4-gm. capacity),

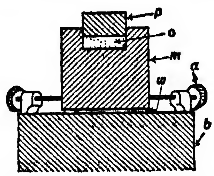

FIG. 91. Drop-weight mortar (*after Gross and Zimmerley*).

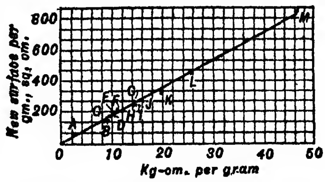

FIG. 92. Grindability of quartz (*after Gross and Zimmerley*).

neatly fitted with a steel plunger *p*, 1/2 in. long. The mortar is centered on a 6(diam.)×8-in. anvil block *b* by three screws *a*. Three aluminum wires *w*, 3.232 mm. in diameter and 1 cm. long, spaced 120° radially, are placed between the mortar and the anvil block. Maximum drop is 60 cm.; 1.3600-, 2.050-, and 2.935-kg. balls were used.

Table 25. Relative grindability by the drop-weight method (*after Gross*)

Material	Surface produced; sq. cm. per ft.-lb.	Relative grindability
Quartz	243	1.00
Pyrite	314	1.29
Sphalerite	779	3.21
Calcite	1,054	4.34
Galena 1	1,256	5.17
Galena 2	1,372	5.65
Ore 1 *a*	507	2.09
Ore 2 *b*	525	2.16

a 15.8% galena, 12.7% sphalerite, 32.8% pyrite, 38.7% gangue.
b 15.9% galena, 14.3% sphalerite, 43.9% pyrite, 25.9% gangue.

Energy absorbed by the aluminum wire was assumed to be denoted by deformation with an unloaded mortar. A smooth calibration curve was obtained. Deformation with a sample in place was measured and the calibrated energy value therefor was deducted from the calculated energy of the drop to give energy input in crushing. In making a test, a weighed sample was moistened with absolute alcohol to prevent dust loss, placed in the crushing chamber, and leveled off; the plunger was in position, the mortar was placed on the aluminum spacers and centered, the ball was suspended at proper height with the suspension cord passing through a guide to prevent lateral displacement on severance; when ball was perfectly quiet, the cord was cut. Thereafter deformation of the aluminum spacers was measured. Surface of the sample before and after crushing was determined by hydrofluoric acid leaching (Art. 17). Results of a number of such tests on quartz are plotted in Fig. 92. The straight line indicates proportionality between calculated energy input and calculated surface; its slope is the grindability of this quartz, 0.25 sq. ft. of new surface per ft.-lb. Martin *et al.* (*25 CerS 63*) using a ball mill for grinding, but a similar dissolution method for surface estimation, arrived at a grindability of 0.0164 sq. ft. per ft.-lb. Table 25 gives relative grindabilities of a number of minerals determined by the drop-weight method. Surfaces for all minerals except quartz were calculated from sizing and elutriation tests, using factors assumed to account for variations in shape and density (*RI 2948*).

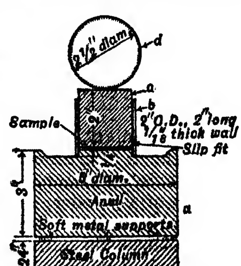

FIG. 93. Wilson drop-weight mortar.

Another drop-weight machine (Wilson, *A TP 810*) is shown in Fig. 93. Anvil *a* is of hardened tool steel machined flat on the lower surface and to the shape shown on the upper surface. The boss is machined to fit snugly but not tightly inside the guide tube *b*. The plunger *c* is made of hardened tool steel, machined to the same diameter as the boss. The surfaces of plunger and boss are polished with fine emery after hardening. Spacers of 1/8-in. solder wire cut in 0.4-in. lengths and slightly flattened to a thickness of 0.1 to 0.11 in. are used. The ball *d* is polished steel; its release is controlled by an electromagnet. Using the Wagner turbidimeter (Art. 17) for surface determination, Wilson reported grindabilities for different clinkers which ranged from 3.54 to 4.94 sq. cm. per kg.-cm.

Pendulum crusher (*154 A 296*) was used by Bond and Maxson to eliminate absorption of energy by the supports of the crushing chamber. The apparatus consisted of a mortar fitted into the pendulum of an Amsler pendulum impact-testing machine. The energy of the falling pendulum was transmitted through a standard test bar, which was broken in tension in each test. Residual energy was

determined by measuring the height to which the pendulum rose after crushing. The procedure necessitates test bars of constant tensile strength, and measurement of residual energy in the pendulum, but Bond and Maxson report close checks on blank determinations with these test bars, somewhat at variance with the normal results in physical testing laboratories. Using the method described in Art. 17 for calculating surface from sizing analyses, Bond and Maxson report the following grindabilities in sq. meters per joule: 0.00339 for NEW CORNELIA ore, 0.00326 for LITTLE LONG LAC ore, 0.002165 for SPRINGS MINES ore, and 0.001315 for petroleum coke from ALCOA, Tenn.

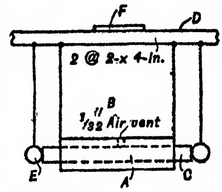

FIG. 94. Pendulum crusher (*after Bond*).

Bond (*PC*) describes a new device (Fig. 94). Crushing chamber *A* is made of round stock, drilled, hardened, and lapped and has a 1/32-in. hole *B* drilled radially at its center. Pistons *C*, made of polished very hard tool steel, fit neatly in the block, which is suspended from frame *D*. Two highly polished hardened steel balls *E* are so suspended that they just touch the piston ends when sample powder is in the crushing zone. Prior to release the balls are held in the horizontal position by means of a string which runs over cutting block *F*. To release, the string is cut by pressing a razor blade against the cutting block. The balls strike simultaneously, thus producing very little movement of the suspended block.

Gaudin (*PC*) describes a device (Fig. 95) consisting of two heavy pendulums *A*, released by electromagnets *B*, which can be set at different positions on circular tracks *C*, thus controlling the height through which the pendulums fall. Mineral samples contained in thin cellophane bags, suspended at the meeting point of the pendulums, are crushed between them. A metal guard *D* surrounds the crushing zone and prevents loss of crushed material, which falls into hopper *E*. Rebound after the first impact is determined by the trace of styli attached to the pendulums. Subsequent collisions are prevented by a weight *F* released by magnet *G* which drops between the pendulums.

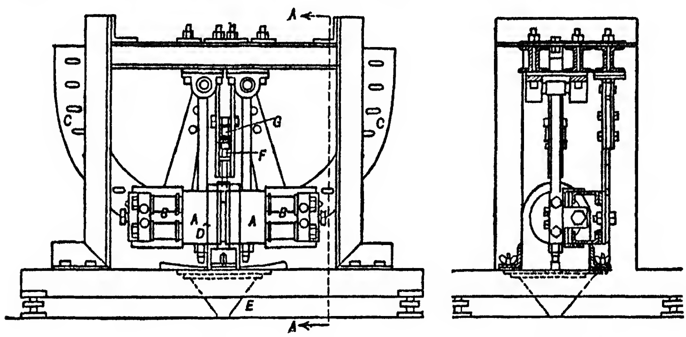

FIG. 95. Pendulum crusher (*after Gaudin*).

Methods assuming constant useful work. Numerous methods have been used to determine grindability wherein the work used in crushing is assumed constant. Lennox (*61 A 237*) used an 8×12 1/2-in. ball mill charged with 3,450 gm. of 3/4-in. balls, 1 lb. of ore prepared to a standardized size distribution, and 1 lb. of water. The mill was rotated for a standard time at 84 r.p.m., after which the product was removed and sized by screens. On the assumption that the energy input to the mill was constant and that a constant fraction thereof was used in crushing, relative grindabilities are equal to the ratios of the surfaces produced. Lennox calculated surface produced on the mesh-ton basis (Art. 19). His results are invalidated by the assumption made that the <200-m. material in the feed has the same surface value as the corresponding weight of <200-m. material in the product, which is not true.

The same assumptions of constancy of work put into the grinding machine by grinding for a definite time, and of constancy of work used in crushing, are made in the A.S.T.M. tests (*D408–37 T*) for grindability of coal. The first test, after Yancey (*108 A 267*), prescribes an 8×8-in. cylindrical ball mill equipped with 3 @ 7/8-in. square lifters and charged with 100 @ 1-in. steel balls and 500 gm. of 10∼200-m. coal. The mill is rotated for a given number of revolutions at a fixed speed. The product is removed and screened on a 200-m. screen; enough <10-m. feed is added to bring the charge to 500 gm. and the previous grind and screening are repeated twice with an intermediate replenishment. The weight of the total <200-m. product in gm. is the grindability. Hertzog *et al.* (*TP 611 USBM*) describe a similar test except that there is no replenishment and the cycles are continued until 80% of the original feed passes the 200-m. screen. The grindability index is the number of revolutions of the mill required to produce this constant fineness.

The second A.S.T.M. test, after Hardgrove (*54 ASME 37*) utilizes a small ball-bearing pulverizer (Sec. 6, Art. 2) with eight 1-in. balls. Ball pressure, supplied by dead weights, is held at 64-lb. total weight. A 50-gm. sample of 16∼30-m. coal is charged and the mill is run for 60 revolutions. Product is screened on a 200-m. sieve. The Hardgrove grindability index is defined as 13 *plus weight of undersize in gm. multiplied by* 6.93.

Coe and Coghill (*RI 3704*) used a form of laboratory dry pan (*149 A 231*) to grind in closed-circuit with an air separator, which could be set to finish at a limiting size as coarse as 28-m. or finer than 400-m. No attempt was made to control circulating load. Hp-hr. per ton required to grind to the same limiting size is their grindability index. Their results are summarized in Table 44, Sec. 5.

Maxson, Cadena, and Bond method (*112 AIME 130*) is a variant of the Yancey procedure, as designed to simulate a dry-grinding ball mill in closed-circuit with a screen under 250% circulating load. Procedure follows: A 40-lb. sample is crushed through rolls in closed-circuit with a 6-m. screen. A sample of the product is placed in a graduate and compacted by shaking to determine bulk weight. A unit volume (700-cc.) is charged to a 12×12-in. cylindrical ball mill, with 285 @ 1 1/2∼3/4-in. balls and ground for a given number of revolutions at 65.8 r.p.m. Contents are removed and screened for 10 min. on the screen at which grindability is to be determined, using a Ro-tap (Art. 12). Screen undersize should be 28.6% of the weight of the unit volume for a circulating load of 250%, and, if it does not amount to this, it is returned to the charge and further ground for a number of revolutions calculated as necessary to produce this percentage, on the basis of the first grind. The product is again screened, and if the undersize is the right percentage, it is removed and the oversize is replenished with original feed to make a unit charge, and is returned to the mill, which is now run for the preceding total number of revolutions. Grindability index is the weight in gm. of material ground through the specified screen per revolution after this weight has become constant.

Rod-mill grindability is tested in a 12×22-in. mill equipped with wave-type liners. The tumbling charge consists of 6 @ 1 1/4×21-in. rods and 2 @ 1 3/4×21-in. rods. Speed is 46 r.p.m. Feed is usually <1/2-in., but with soft ores may be coarser. Unit charge is 1,250-cc. of dry solids, compacted by shaking. Tests are run at a 100% circulating load. The mill is so mounted that it can be tilted through a complete circle; it is discharged through a trunnion bearing and a grate which retains the rods. In operation, the mill is tilted, at 10-revolution intervals, 5° in one direction for one revolution and 5° in the other direction for one revolution, to prevent escape from grinding by lodgment between the ends of the rods and the heads of the mill. Procedure is the same as in ball-mill grindability testing.

Results of many tests are given in Tables 46 and 47, Sec. 5.

Validity of the per cent.-passing grindability unit determined in a given machine under constant conditions of operation depends upon the validity of three assumptions, *viz.*, (*a*) energy input per revolution is constant, (*b*) the same fraction of this energy is used in grinding, regardless of the nature of the material, and (*c*) the undersize of a given screen has the same surface per unit of weight irrespective of the material. Bond's calculation of surface (see Art. 18) hinges on the assumption of a grind limit. Using this method Bond and Maxson (*112 A 146*) calculated that the energy per revolution consumed in crushing was constant to within 10% regardless of the screen size used in the determination, the circulating load, and the nature of the material (see Table 26). Assumption *b* has thus been shown to be reasonably correct; consequently the validity of assumption *a* is of less concern, though even this assumption is probably correct under the conditions of this test (*RI 3056*).

Efficiency of ball mill operation has been calculated by Bond and Maxson, Gross and Zimmerley, and Wilson *et al.* (*loc. cit.*) on the basis of grindability indexes. The method follows: Net surface production of the mill is determined by measurement or by calculation from screen analyses. This figure is divided by the grindability expressed in units of surface per unit of work, the result being total energy used in grinding. The energy input to the mill is determined from power readings on the motor driving the mill, or more directly by a Prony brake or the Gross and Zimmerley integrator (*RI 3056*). The ratio of energy used in crushing to the energy input is defined as efficiency. Some investigators subtract the energy consumed by the empty mill from the input energy and use the difference in the efficiency calculation. Gross (*loc. cit.*) applied this method to a 2-stage plant circuit grinding an ore consisting of galena, sphalerite, and pyrite in a siliceous gangue and obtained efficiencies of 47% for the primary and 42% for the secondary mill. His grindability index was based on a drop-weight figure for quartz. Bond and Maxson (*loc. cit.*) cite an average figure of 64% for commercial closed-circuit wet grinding. Wilson's figures (*loc. cit.*) for grinding clinker range from 20 to 43%. These figures stand or fall upon the correctness of the assumption that grindabilities determined by the drop-weight or impact-tester methods are the same as grindabilities determined in some other device

wherein the method of breaking more nearly simulates comminution in the ball mill There is no direct evidence in favor of this assumption; it would appear invalid, since the strength of materials varies according to whether they are loaded in compression, tension, or shear.

a Calculated by Eq. 79, using values of slope given in preceding column.
b Obtained by multiplying sq. meters per revolution by grindability of ore as given in Sec. 5, Tables 46, 47.

Selection of grinding mills is based upon relative grindabilities and operating performances. The ore for which a grinding mill is to be chosen is compared, by means of grindability tests, to other ores for which complete performance data are available. It is thus located between two ores on the grindability scale. From performance data on the reference ores the total energy required to grind the desired tonnage to the desired *mog* is obtained by interpolation. This energy divided by the time allowed for grinding the desired tonnage gives the power required to drive the prospective mill. A mill, or mills, drawing this power is then selected. Its type and proportions are based on other considerations (see Secs. 5, 6).

SIZE TESTING

Sizing analyses may comprise either physical separation of a mass of particles of mixed sizes into grades, each of which is characterized by a relatively small size interval between the largest and smallest particles; or the making of measurements, without actual physical separation, in such a way that by proper methods of interpretation they may be translated into statements of size and size distribution. Methods of physical separation are (*a*) screening and (*b*) elutriation; methods not involving actual separation are (*c*) microscopic sizing, (*d*) sedimentation, and (*e*) various methods for estimating surface, *e.g.*, turbidimetry, Tyndallometry, surface reaction, surface friction, and surface electrical effects. By these methods a complete size analysis can be made, ranging from any maximum down to molecular dimensions; measurement by calipers or the like is applicable from any maximum to about 3- or 4-in.; sieving applies from 3- or 4-in. to about 37-μ; elutriation, from 50- or 60-μ to about 3- or 5-μ; sedimentation, from 5- or 10-μ to about 1-μ; centrifuging, from, say, 2-μ to molecular dimensions. If liquids other than water are used in elutriation or sedimentation the limits may be changed.

There is no direct method of sizing. Microscopic measurement comes nearest to the absolute; its failure is not methodological but is due to inability, on the part of the operator, to specify what dimension is measured. Each irregular fragment has an infinity of dimensions, and if one is chosen for a particular grain it is ordinarily impossible to specify the corresponding dimension in another grain. Maximum and/or minimum dimensions can be specified, but their measurement is uncertain. Sieving is sometimes called a direct method of sizing, yet it is sought only to place a particle in a group the upper and lower limits of which are specified. The dimension presumed to be measured is the intermediate. Other methods of sizing seek to place a grain in a group such that its settling velocity in a fluid shall fall between specified limits. Size measurement is then obtained by calculating the diameter of a sphere having a falling velocity in the fluid the same as that of the particle. Since the dependence of velocity upon size, shape, density, etc., is not too well known, the results are approximations at best.

12. SCREEN ANALYSIS

Testing sieves used for screen analysis are circular pans, 6 to 18 in. diameter and 1 to 3 $^1/_4$ in. deep, with screen bottom. The frame is ordinarily made of brass with upper edge beaded on a stout wire and lower edge extended beyond the screen, crimped inward, and rolled to an easy fit with the upper edge of the other screens in the set, in order that the screens may be nested. Pans to collect undersize and covers to confine oversize may also be obtained; their use decreases dust loss. TELESCOPE NESTS, usually made with each finer screen of sufficiently smaller diameter than the preceding to permit telescopic packing, are made for field use. The pan of a telescope set is of such diameter as to receive the nested set.

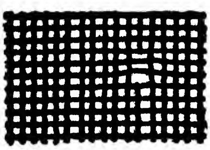

FIG. 96. Microphotograph of 200-m. screen cloth, magnified 12.5 diameters (warp wires vertical).

Standard testing sieves. The U. S. Bureau of Standards has done considerable work in the study of fine testing sieves and their performance in connection with the determination of the fineness of cement. The work early showed the irregularities in fine cloth (Fig. 96) and the first specification of a standard was designed to overcome these irregularities by setting up tolerances in diameter of wire and their spacing (*USBS Circ. 39*). Subsequent specifications (*USBS TP 29, 42*) allowed larger tolerances as to mechanical construction, placing emphasis on performance. Recent specifications covering woven-wire sieves, round-hole screens and square-hole perforated plate screens for precision testing are *ASA No. Z 23.1-1939* and *ASTM E 11-39*.

Specifications for woven-wire sieves:

(*a*) Woven cloth for standard sieves shall be woven (not twilled, except the cloth of the 62-, 53-, 44-, and 37-micron sieves) from brass, bronze, or other suitable wire and shall not be coated or plated.

(*b*) The average opening between the adjacent warp and the adjacent shoot wires, taken separately, shall conform to that given in column 2 of Table 27, within the "permissible variation in average opening" given in column 4. Column 3 gives the approximate equivalent in inches of the basic values in millimeters given in column 2. The average diameter of the warp and of the shoot wires, taken separately, of the cloth of any given sieve shall be within the limits given in column 6. Column 7 gives the approx. equivalents in inches of the basic values in millimeters given in column 6. The maximum width of opening between adjacent warp and shoot wires shall not exceed the nominal width of opening by more than the "permissible variation in maximum opening" given in column 5. An exception may be made, in the case of 8-in. sieves, if the total length of all the portions of rows of openings exceeding this minimum width is less than 4 in. in both the warp and shoot directions, considered separately, provided that the sieve is not rejected under Paragraph (*d*). For sieves from 1,000-micron (No. 18) to the 37-micron (No. 400) size, inclusive, not more than 5 per cent. of the openings shall exceed the nominal opening by more than one-half of the permissible variation in maximum openings.

(*c*) Both the warp and shoot wires shall be crimped in such a manner that they will be rigid when in use.

(*d*) There shall be no punctures or other obvious defects in the cloth.

Calibration of woven-wire sieves. The method employed by the Bureau of Standards is detailed in the appendix to the above cited standard. The Bureau of Standards will test sieves to determine conformity to specifications.

Sieve scales. If a piece of substantially homogeneous rock is broken by any of the usual methods of crushing and the product divided into a number of grades according to size, it is found that the weights of the grades change gradually from size to size (Fig. 97), that they pass through a maximum in one of the coarser sizes, and, sometimes, through a

[a] Permissible variations in average openings.

secondary maximum near the fine end, whereas the weight of the undersize of the finest screen is usually greater than that of the last preceding grades. This behavior is apparently a natural characteristic of crushed homogeneous material. The location of the maximum point in the curve varies with the extent of the size reduction, the method of crushing, and perhaps other factors. If the rock is nonhomogeneous, the secondary maximum is usually more pronounced and its position distinctly related to the rock structure, whereas the location of the principal maximum differs from that of a homogeneous rock similarly treated. As the number of grades is decreased, the smoothness of the curves decreases and a small amount of experimental work makes it apparent that irregular intervals between successive grade sizes increases the irregularity of the results. While this is an *ex post facto* explanation, it is the principal physical justification for a testing-sieve scale with regular size intervals. Various testing-sieve scales have been proposed (*Ed. 1, 1183*) but today the use of the Tyler series is almost universal.

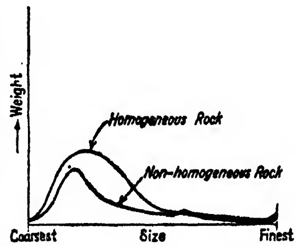

FIG. 97. Direct plots of sizing tests of homogeneous and nonhomogeneous rock powders.

Tyler series is a geometrical progression with the multiplier $\sqrt{2}$ (= 1.414); it starts from the standard 200-m. testing sieve (0.0029-in. = 0.074-mm. = 74-micron). This screen has long been established in testing-sieve practice and standardized by the U. S. Bureau of Standards. The 20-m. (0.833 mm.) and 100-m. (0.147-mm.) screens of this series have also been standardized by the Bureau. The screens have been adopted worldwide, hence published screen tests of results at one mill can be interpreted in terms of screens familiar to readers at other mills practically everywhere. The manufacturers also make sieves to the $\sqrt[4]{2}$ ratio, in order to give closer sizing, if desired. This series also starts at the standard 200-m., hence fills in the gaps between the screens in the regular series.

U. S. series (A.S.T.M. STANDARD) also uses the $\sqrt{2}$ ratio but is based on a 1-mm. (= 1,000-μ) opening. Owing to the range of permissible wire diameters established in 1938 this series can now be used interchangeably with the Tyler Standard Sieve series.

British Engineering Standards Association series (B.S. SERIES) (*32 CEMR 357*) adopted in 1932 supersedes the old I.M.M. series. The openings in the B.S. screens follow closely those in the Tyler series; the slight differences stem from the specification of British Standard wire diameters.

Table 28 gives the mesh and apertures of the Tyler, U. S., and B.S. testing sieves.

Screens for coal testing. Holbrook and Fraser (*Bul 234, USBM*) call attention to the fact that the standard testing-sieve scales are not useful for ordinary coal testing for several reasons, *viz.:* (1) They include such fine screens that woven-wire screen surface must be used, whereas most commercial coal preparation is done on round-hole screens to which testing sieves must correspond. (2) The series are based on the metric system, whereas coal is sold in sizes commonly rated in common (English) units. (3) The majority of screens in the proposed scales are below 1-mm., whereas the interest in coal investigations is usually in coarser sizes. (4) The usual testing sieves have 8-in. frames; coal testing, involving as it does much coarser material, requires larger samples than ore testing and consequently larger sieves.

Table 29. Thickness of plates for round-hole screens

Screening area, sq. in.	Diameter of opening, in.	Thickness of plate, in. Minimum	Thickness of plate, in. Maximum
Under 100....	All sizes	0.049	0.066
100 and over	1/16 and 1/8	0.049	0.066
	1/4 to 2 1/2, incl.	0.060	0.100
	3 and 3 1/2	0.075	0.130
	4 and 5	0.105	0.160
	6 and 8	0.120	0.175

Specifications for round-hole plate screens were adopted by the A.S.A. in 1939 (*ASTM E 11-39*), as follows:

Plates used in manufacture of round-hole screens shall be made of brass, bronze, steel or other rigid metal. Thickness of plate shall be governed by size of opening as well as screening area of screens and shall conform to the requirements prescribed in Table 29.

Frames for laboratory screens shall be at least 8-in. in diameter. Frames for standard 8-in. laboratory screens shall conform to the requirements specified in Section 3 for woven-wire cloth sieves. Frames for large screens may be made of either hardwood or metal and may be square, rectangular, or circular as specified. For screens having circular openings 1-in. in diameter or larger, frames larger than 8-in. in diameter are recommended.

(a) Spacings of openings shall conform to the following requirements:

Nominal diameter of opening, in.	Nominal width of metal between adjacent openings, in.	Nominal diameter of opening, in.	Nominal width of metal between adjacent openings, in.	Nominal diameter of opening, in.	Nominal width of metal between adjacent openings, in.
1/16	3/64	7/8	1/4	3	3/4
1/8	3/32	1	3/8	3 1/2	3/4
1/4	1/8	1 1/4	3/8	4	3/4
3/8	3/16	1 1/2	1/2	5	1
1/2	3/16	2	5/8	6	1
5/8	3/16	2 1/2	3/4	8	1
3/4	1/4				

(b) The openings shall be so arranged that their centers lie at the vertices of triangles which are approx. equilateral within the limits given by the permissible variations in width of metal and diameter of opening.

Permissible variations for openings and spacings:

(a) For screens having openings 1/4-in. or less in diameter, the actual diameter of any opening shall not vary from the nominal diameter by more than plus or minus 5%.

(b) For screens having openings over 1/4-in. in diameter, the actual diameter of any opening shall not vary from the nominal diameter by more than plus or minus 3%.

(c) The width of metal between adjacent openings in the screen plate shall not vary from the nominal value by more than plus or minus 20%.

Screens for pulverized coal may be the usual square-mesh wire-cloth sieves.

Methods of screen analysis. Rough analyses, suitable for all ordinary work, are made by placing a weighed dry sample of the material to be tested on the top or coarse screen of a nest (scale ratio, $\sqrt{2}:1$), shaking the nest until most of the undersize has passed the coarse screens (1 or 2 min.), then removing the screens one at a time, beginning at the top, shaking each separately over a pan until the amount passing through in a minute is less than 1% of that remaining on the screen. Undersize is added to the top screen of the remaining nest. On coarse screens (0.75-in. or larger apertures) pieces near the screen size may justifiably be tested and put through, if possible, by hand. Oversizes and final undersize should be weighed and kept separate until all have been weighed and the weight checked against the original weight. Weighings should be accurate to within 1 to 2% and the total weight of the grades should check the original weight of the sample within 2%. Screens should be shaken in such a way that the material is caused to travel slowly in a thin sheet over the whole surface of the sieve and at the same time the sieve should be jarred in a way that will cause the cloth to vibrate in a direction perpendicular to its plane. In specifying a standard method for sieve testing of cement, the U. S. Bureau of Standards states that the sieve "shall be held in one hand in a slightly inclined position · · ·, at the same time gently striking the side about 150 times per min. against the palm of the other hand on the up stroke. The sieve shall be turned every 25 strokes about one-sixth of a revolution in the same direction." The reason for the final specification appears in some work by Griesenauer (*70 EN 1296*) showing a variation of 1.4% in the mean of tests across warp and shoot wires. Machine shaking may, of course, be substituted for hand shaking. When the fine material is caked, it may be broken up by rubbing on the sieve with a bristle brush or a rubber cork. Cut-metal washers are sometimes placed on the finer sieves during shaking, but this practice wears and distorts the fine cloth and, with soft material, produces an improperly large amount in the finest size.

When coarse material is tested the sample must be large because of the impossibility of cutting down accurately (Art. 1). On the other hand, except for the most accurate work, a carefully riffled sample of <0.12-in. material weighing 250 to 300 gm. is large enough. Hence considerable time can be saved by sifting the large sample roughly on the 3.33-mm. screen, cutting down the undersize to 250 to 300 gm., and screening this on the finer screens while the oversize is rescreened beginning with the coarsest screen. The undersize from the 3.33-mm. screen on the rescreening may usually be considered oversize on the next finer screen and so treated in calculating the redistribution.

Wet preliminary splitting is employed for reasonably precise routine mill and laboratory samples. The method comprises a preliminary wash of the sample, including subjection of the washings to the 200-m. screen; drying the oversize; screening oversize on a nest of screens down to and including 200-m. in a mechanical test-sieve shaker, and adding the dry undersize of the 200-m. screen to the undersize from wet screening. SAMPLE WEIGHTS should be about 1,000 gm. for material from 4-m. to 10-m. limiting; 500 gm. for 14-m. to 28-m. maximum; 200 gm. for 35-m. and finer. SCREENING TIME is determined by the finest screen in the nest and by the type of sieve shaker; 15 min. for 200-m. screens, 10 min. for 100-m. is normally sufficient; friable ores should be shaken shorter times, say 10 and 7 min. respectively. Losses of 0.5 to 1.0% may be expected; these are usually distributed to the

various sizes according to their weight, but observation indicates that maximum loss is in the finer sizes and the basis of adjustment should be changed accordingly.

Weighing of sample fractions may be simplified greatly by adopting some such routine as the following.

(*a*) Starting with the coarsest screen, remove oversize from screen by inverting the latter over a pan. (If this operation is performed over glazed paper of a color that contrasts with the particles, spill losses will be reduced.) Dislodge material lightly caught in screen meshes by pressure of a finger for coarse screens, by means of a stiff brush applied to the underside of finer screens, and add the dislodged material to the oversize. Brush the dust from the screen onto the next finer screen, using a camel's-hair brush. Place the screen, in inverted position, at a convenient point on the work bench.

(*b*) Transfer the material from the pan to a scoop, such as Fig. 98, and thence to a suitable sample pan, using the camel's-hair brush to control the rate of flow of the material and thus prevent spill. Place the pans in order in a position adjacent the scales.

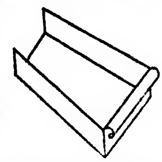

FIG. 98. Transfer scoop.

(*c*) After all of the grades have been transferred from screens to pans, weigh on pulp scales of suitable capacity, starting with the coarsest grade. Transfer from sample pan to scale pan should be made via the scoop, as above described, dusting carefully with the camel's-hair brush after each transfer. After each weighing return sample to its own sample pan, retaining the sample until all weighing is completed and a check can be obtained with the original sample weight.

(*d*) Check the record of screen sizes against the inverted stack of screens. Samples may now be discarded, provided no further use of them is contemplated.

Wet samples should not be dried before screen testing until the slime has been removed by passing it through the finest screen of the series to be used, if maximum accuracy in estimation of fines is desired. WET SCREENING is best done by jigging light loads on the fine screen at the surface of water in an enameled pail, and washing the material on the screen with a fine jet until substantially all of the slime has passed. Oversize is then dried and rescreened on a nest including the fine screen, and the undersize of the fine screen on dry sifting is added to the dried undersize of the wet screening. This procedure is quicker and more accurate than preliminary drying and dry sifting, on account of the difficulty in breaking up slime cake formed in drying. Sampling wet pulp for the screen sample is, however, a difficult matter, and this consideration may justify drying, riffling, and subsequent wetting to break slime cake.

Standard sizing test (*ASA M5–1932*, revised) prescribes as follows:

Sieves shall be 8-in. diameter, with well-fitting pan and cover, all free from crevices wherein particles can lodge. Sieve-scale ratio must not exceed $\sqrt{2}$: 1. It is recommended that sieving be carried to 37-μ.

Preparation of sample. Dry thoroughly at 110° C., mix well, and divide by riffing to an amount within 10% of the standard charge (see below). Adjustment of an exact weight may be made by adding to or subtracting from this split, but it is preferable to take the entire split.

Table 30. Standard sample weights for screen analyses

Limiting particle size, mm.	Standard charge, gm.
16.00 to 11.32	40,000
11.32 to 8.00	12,500
8.00 to 5.66	5,000
5.66 to 4.00	2,000
4.00 to 2.00	1,000
2.00 to 1.00	500
1.00 to 0.50	250
0.50 to 0.25	100
0.25 to 0.00	50

Size of sample. See Table 30. DOUBLE-SIZE CHARGES may be screened by making two sizing tests and combining like products.

Wet splits. Sieve wet through the finest sieve, preferably using distilled water, either by decanting through the sieve or by direct wet sieving, until all of the slime is removed. Dry undersize and oversize at 110° C., cool, and weigh. Add any loss in weight to the fine undersize.

Standard hand-sieving manipulation. Work over a smooth paper to indicate spills. Hold the sieve, with pan and cover in place, slightly inclined in one hand, and, with a stroke of 6 to 8 in., strike gently against the other hand 150 times per min., turning the sieve one-sixth revolution after each 25 strokes, thus completing a revolution in 1 min. This operation is called a 1-min. period. If the 37-μ sieve is used, a 6-in. frame is recommended; at 200 s.p.m. turning one-eighth revolution after each 25 strokes, agitation is equivalent to that prescribed for the 8-in. sieve.

End point is reached when less than 0.05% of the weight of the original charge passes through the sieve in a 1-min. period.

Oversize from wet split, after drying and weighing, is sieved dry on the finest sieve until the undersize for a 1-min. period is less than 0.1% of the original weight of the charge. Brush both sides of the sieve to remove dust and loosely held particles in the meshes. Return the oversize to the sieve, and continue sieving until the undersize for a 1-min. period is less than 0.05%. Repeat the brushing, and sift for another 1-min. period. If undersize is again less than 0.05%, return it to the oversize; if it is more than 0.05%, continue sieving until a 1-min. period gives less than 0.05%. All undersize of the finest sieve is weighed and added to the undersize from the wet split.

Collection of oversize. [Pour onto glazed paper or into a pan.] Clean the sieve by tapping sides, brushing, and by rubbing with a flat rubber [all over glazed paper]. Add material obtained by cleaning to the oversize, which is weighed. Loss is added to the undersize of the particular sieving in which it

occurred. Total loss for the entire sieving operation should not exceed 1% of the weight of the original sample. [Bracketed material added by *Ed.*]

Optional Methods

Separating sub-sieve sizes. No method or apparatus is recommended as standard. Whether sedimentation or elutriation is employed, the operation must be carried on at a definite temperature (20° C. is suggested); the sample must be thoroughly dispersed; distilled water is preferable.

Table 31. Tentative settling-rate size equivalents

Size range, μ	Arithmetical average size, μ	Falling velocity, mm. per sec. for		Time from start during which this product is collected after 1-meter fall, min.
		Coarse	Fine	
74~52 *a*	63.0	3.6	1.8	0 to 9
52~37 *b*	44.5	1.8	1.0	9 to 17
37~26	31.5	1.0	0.5	17 to 33
26~18.5	22.2	0.5	0.22	33 to 76
18.5~13	15.8	0.22	0.13	76 to 128
13~9.2	11.1	0.13	0.08	128 to 210
9.2~6.5	7.9	0.08	0.05	210 to 330
6.5~4.6	5.6	0.05	0.03	330 to 560

a Equivalent to 200~270-m.

b Equivalent to 270~400-m. The particles for each settling interval may be measured by means of the microscope, from which the average size may be calculated. No method for the microscopic measurement is recommended as a standard. Sub-sieve sizes, if not actually measured, are reported as products settled 1 meter for a definite time period.

Settling-rate size equivalents based on Richards' figures for quartz are given in Table 31. Equivalents based on Stokes' law are widely used.

Sieving the coarser sizes first, after the wet split has been made on the finest sieve, is optional. Carry to end points described under *Oversize from wet split.* Loss is included in the undersize of the finest sieve.

Material that disintegrates or alters when wetted is sieved dry. Proceed as described under *Oversize from wet split.* Each size must be lightly brushed on the sieve to free the particles from adhering dust before being considered completely sieved. Measurement of sub-sieve sizes may be made as described by Perrott and Kinney (*6 #2 CerS 417*), embedding the material in Canada balsam containing 20% xylol, between two slides and making a microscopic count and measurement (see Art. 9).

Material that decrepitates below 110° C. must be wet sized, starting with an unknown charge weight if moisture determination is not feasible. In this case the total weight of the products must be considered the original charge weight, hence loss in sizing cannot be determined. End point must be determined by judgment of the amount passing through the sieve in 1 min.; this is not sufficiently accurate for a standard, hence wet sizing is not recommended except where dry sieving is impracticable.

Machine sieving for 1-min. intervals may be substituted for the 1-min. hand-sieving periods. Machine analyses may be made using a nest of sieves. The sample must first be wet split by hand on the finest sieve. Dried oversize is sieved for 30 min., with possible 20-min. and 10-min. successive subsequent periods. After the 30-min. period the sieves are cleaned and progress checked by hand sieving as follows: Starting with the coarsest oversize, weigh, then hand-sieve for a 1-min. period. If undersize is less than 0.05% of the original weight, sieving for this size is considered complete; if between 0.05 and 0.1%, sieving is completed by hand; if more than 0.1%, machine sieving is continued 20 min. After the 20-min. period, check by hand as before, and, if necessary, sieve further for 10 min. After the 10-min. period, finish all sizes by hand. Loss must be reported as "loss in weight," but should be included in the percentage of undersize from the finest sieve.

Comment. Apart from the excessive time required for this procedure the principal faults are (*a*) the large sample weights recommended, and (*b*) sifting the dry material on progressively coarser screens. Duplicate screen tests of 10-kg. shovel samples of <16-mm. material check well within the limits of the differences in sifting by two different operators, and the same is true of samples of <0.12-in. material weighing between 250 and 300 gm. Placing coarse oversize on fine screens is equivalent to the use of metal washers, which is universally and rightly condemned. It is questionable whether any of the ends served by sieve analysis justify this elaborate procedure. It is useful, however, as a standard of comparison for the often less than adequate procedures in commercial use.

Standard sizing tests for powdered coal (*ASTM D 197–30*), anthracite (*ASTM D 310–34*), and for bituminous coal (*ASTM D 311–30*) have also been approved by the A.S.T.M. In addition to the screening method to be followed, these standards specify the manner of collecting a gross sample and the procedure to be followed in the preparation of the laboratory sample.

Shape screening is important in testing concrete aggregates, owing to the fact that aggregate packs more compactly the more closely it approaches equiaxial shape, and that the corresponding saving in cement may amount to as much as 5 to 10%. Shape screening is performed by screening first on square (or round) holes, and rescreening oversizes successively on rectangular slotted screens. Sheppard (*RI 3432*) rescreened the oversizes of square-mesh woven-wire sieves on rectangular slotted screens, so selected that the widths of the openings were one-half and one-third of the side of the square opening, and the length was greater than the diagonal of the square opening. Table 32 shows the results of a shape-screening test on limestone. If width is less than twice the thickness, particles are rated CUBICAL; if width is >2 <3 times thickness, rating is INTERMEDIATE;

a Determined by direct measurement.

if width is more than three times thickness, rating is SLABBY. Table 33 gives the weighted average ratios of particle length and width to thickness.

Correction of screens has been attempted by several workers. Sizing tests of commercial products are necessarily empirical and in order to obtain reproducible results all conditions must be standardized. Despite standardization, however, it is frequently impossible to obtain comparable results under apparently identical conditions. The primary cause of disparity is that retention from a given material on two nominally equivalent screens may differ by as much as 20%, and on two certified equivalent screens by as much as 5%. This is due to (*a*) the wide tolerances permitted in the A.S.T.M. standard specifications (see Table 27), and (*b*) the method used in certifying conformity.

Table 33. Weighted average ratios of particle length and width to thickness of product from Table 32

a Weighted according to weights shown in Table 32.

Weber and Moran (*10 IECA 180*) showed that screens with the same average opening but with different standard deviations gave different retentions. They noted that sieves with relatively large dispersion of size of opening always behaved as if the average opening was somewhat larger than that calculated from microscopic measurements of opening. The difference between the average opening of a sieve with high dispersion and that of a sieve having equal retention but small dispersion increases as the standard deviation of the former increases above 6%. This effect of the relatively larger proportion of oversized openings in a sieve with large dispersion increases as the shaking time increases, since more opportunity is provided slightly oversized particles to pass these oversized openings. Weber and Moran proposed an empirical equation for the correction of screen aperture, *i.e.*,

$$X_t = \bar{X}\left[1 + 0.002t\left(\frac{d-6}{0.06}\right)^{1/2}\right] \qquad ([illegible])$$

is the effective opening for a shaking time of t min., $\bar{X}$ is the arithmetic mean of the microscopically measured openings, t is time in minutes, d $\left(= \frac{100\sigma}{\bar{X}}\right)$ is the per cent. standard deviation (σ is the standard deviation) or the coefficient of dispersion (or variation).

Bond and Maxson (*134 A 301*) propose a method of correction based on the size-distribution curve normally associated with a crushed or ground homogeneous material. This curve, obtained by plotting the logarithm of the per cent. weight retained upon each screen in the Tyler standard series against the ordinal number of the screen (see Art. 24) is linear, if the first three or four ordinal numbers (beginning at the largest particle) are disregarded. To correct a set of screens, petroleum coke crushed to <6-m. is screen-analyzed. The correct per cent. weight retained on 200-m. is determined with a special standardized screen. Assuming that the coarse screens vary little if any from their designated size (experience supports this assumption) a straight line is drawn between the correct 200-m. point and the coarse screen. The plotted results of the screen analysis in general do not fall on the line so determined. A correction factor is calculated to make the resulting log per cent. weight fall on the distribution line. This correction factor is subsequently applied to all screen analyses performed with this set.

Hatch (*215 JFI 27*) also proposed a correction based on the size-distribution curve. His factor is applied to the designated aperture in such a fashion as to bring the actual distribution curve into congruence with the normal probability curve (see Art. 1). Since the Hatch method of correction does not depend upon the distribution curve of a standard material but upon the distribution curve of the material under test, it is applicable only to materials whose size-frequency distribution follows the normal law.

Protection of good screens is readily accomplished by use of two screens of the same mesh, placing the old one above the new one. The load is placed on the old screen, which passes all but difficult grains easily. Due to enlarged apertures difficult grains will pass the old screen more readily, and the old screen may also pass oversize. Difficult grains and oversize passing the old screen are caught on new screen and are there sized where openings are not deformed and the surface is not overloaded.

Mechanical testing-sieve shakers. It requires from 1 to 3 hr. to sift a 200-gm. sample containing 30 to 50 gm. of <200-m. material by manual shaking. Mechanical shaking reduces the time to from 30 to 45 min. and during the time the sieves are being shaken the operator is free for other laboratory duties.

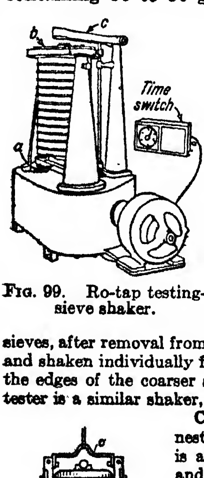

FIG. 99. Ro-tap testing-sieve shaker.

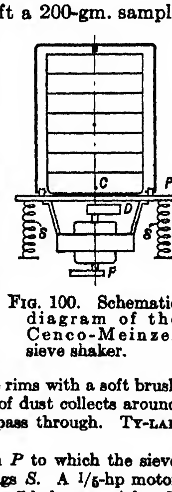

FIG. 100. Schematic diagram of the Cenco-Meinzer sieve shaker.

Ro-tap testing-sieve shaker (Fig. 99), for 8-in. testing sieves, consists of a movable cage with base *a* and top plate *b* between which a nest of 13 half-height sieves or 7 full-height with pan and cover can be mounted and subjected to a rotary sifting motion while at the same time the lever *c* strikes the top plate once per revolution and produces vibration of the screen cloth. A time switch on the motor is useful. Duplicate samples sifted for equal periods of time on the same or different machines check well within the limits of sampling error. If the total amount of dust in the sample is important, the sieves, after removal from the shaker, should be brushed around the inside of the rims with a soft brush and shaken individually for a short time as in hand sifting, as a small amount of dust collects around the edges of the coarser screens during the mechanical shaking and does not pass through. TY-LAB tester is a similar shaker, without tapper, for square screen frames.

Cenco-Meinzer shaker (Fig. 100) comprises a platform *P* to which the sieve nest is clamped. This is supported by four helical springs *S*. A $^1/_6$-hp motor is attached to the underside of the platform. It carries off-balance weights *D* and *F* at the ends of its shaft. The motion is essentially horizontal gyratory, with a vertical component which depends upon the location of the center of mass, *C*, of the system.

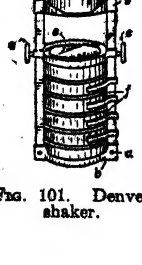

FIG. 101. Denver shaker.

Denver shaker (Fig. 101) is of unbalanced-pulley type. It consists of two square hardwood members *a* bolted at the bottom to a plate *b* recessed to seat standard 8-in. sieves, and at the top to a metal hanger *c*. A $^1/_6$-hp. motor is bolted to the uprights near the top; its shaft carries an unbalanced pulley enclosed in the housing *d*. The sieve nest is placed between the base plate and a top plate *e* which is held firmly in position by tightening hand wheels *e*. Fingers *f* carried on one of the uprights prevent buckling of the nest. The assembly is suspended by a rope or rod from *c*. Rotation of the unbalanced pulley causes circular vibration of small amplitude in the clamp *g*. This is amplified by the resilience of members *a*, particularly at the bottom where the weight is least, and this motion is transmitted to the screen nest.

Home-made shakers can be devised by any one with a modicum of mechanical imagination.

A simple form (*RI 3538*) is made by fitting a handle to the pan of a sieve set, slotting the end of the handle to fit over an adjustable crank pin at the end of a shaft (about 500 r.p.m.) mounted horizontally at a height above a table top equal to the height of the center line of the pan handle above the pan bottom. Screen and cover are held to the pan by heavy rubber bands, and other bands anchor the screen assembly to a post in the table top. Nature of the motion depends upon the amplitude of the crank, the play in the crank slot, the location of the anchor pin with respect to the screen assembly, and the placing of the anchor bands. Time for screening in the 65- to 400-m. range is reported as 1 to 10 min.

Mechanical vibrator (Fig. 102) reported to screen more rapidly than the manufactured gyrating types (*RI 2933*) consists of a table *a* hinged at one end to foundation blocks *b* and held down at the other end against a bumping block *c* by a spring *d*. A sieve assembled with pan and cover *e* fits into a cleated space on the table as shown and is held down by a spring clamp *f*. Vibration is imparted to the table by means of a 4-tooth sprocket *g* carried under the center by a shaft supported by blocks *h* and driven by pulley *i* at about 300 r.p.m. Amplitude is controlled by a micrometer screw *j* set in the top of *c*.

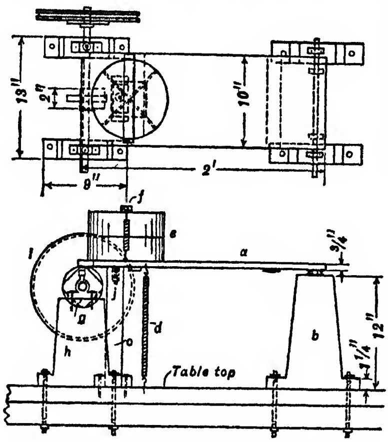

FIG. 102. Homemade mechanical vibrator.

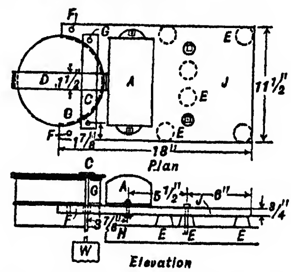

FIG. 103. Shaker with Syntron vibrator.

Magnetic vibrator *A* (Fig. 103) is used (*141 #9 J 58*) to vibrate a hardwood board *J* bolted against interposed rubber stoppers *E* to a firm base *H*. Board *J* is cut out as shown to receive the sieve nest. A frame comprising crossed straps *C* and *D*, welded together, and two 1/4-in. bolts *G* carrying counterweight cylinders *W* filled with lead shot press cover and sieves down on the pan, which is supported by its rim against board *J* and is held in place by 5/32-in. rubber tubing with 1/16-in. wall, threaded through holes *F*. Counterweights and frame weigh 10 lb. Bolts *G* are made long enough so that 10 high-wall sieves and a pan may be taken at once. A V-9 Syntron electric vibrator *A* with an electric controller was used.

13. ELUTRIATION WITH LIQUIDS

Elutriation is the process of grading sub-sieve sizes (usually <200-m.) into equal-settling grades in a fluid such as water or air. If the material is predominantly of one specific gravity, and the work is carefully done, the resulting grades can be made remarkably uniform by taking small settling intervals; but with widely different gravities or with marked grain-size differences, considerable size variation occurs, even with small intervals.

Decantation is the simplest method of elutriation.

Procedure. Take a tall beaker of 800- to 1,000-cc. capacity, place therein the sample to be sized, which should be of such weight that the concentration of solids does not exceed 5% by weight when the beaker is filled with water to a predetermined depth (say 10 to 20 cm.), stir thoroughly, and allow the beaker to stand for such a time that its duration in seconds divided by the depth of water in millimeters equals a predetermined settling rate corresponding to the largest particle desired in the grade. Required time may be read from Fig. 104 (see also Fig. 2, Sec. 8), or be determined by application of Stokes' equation (Sec. 8, Art. 1). Pour off supernatant liquid with

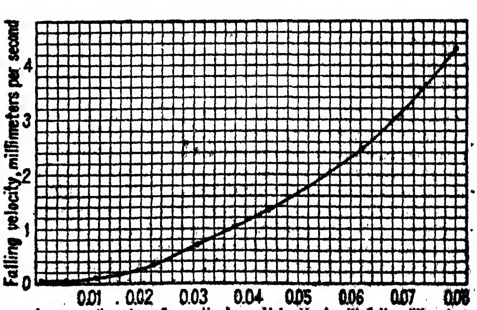

FIG. 104. Free-falling velocities of fine quartz (*after Richards*).

nonsettled solid in suspension, refill to the mark and again allow to settle for the same time. Repeat this until the appearance of the supernatant liquid indicates that all of the finest slime has been removed. Combine the decanted portions, take a sample, while wet, for microscopic determination of size (Art. 9), then dry at 110° C., cool, and weigh. Refill the beaker to the mark with fresh water, and repeat the above operations, allowing a shorter time for settling corresponding to the next coarser grade desired. Repeat as above until the desired number of grades is obtained. If there is obvious chemical action during the operation, using tap water, *e.g.*, formation of gelatinous precipitates, distilled water should be used. If this does not remedy the trouble, weak solutions of acid, alkali, or a salt may be used, but in such cases the presence of the added chemicals in the dried solid must be recognized. If microscopic sizing of the different grades is dispensed with, it must be recognized that there is considerable overlapping of sizes, due to the fact that not all of the solids start settling from the surface of the liquid in the beaker and that some particles that start settling from a point below the surface will reach bottom while coarser particles starting above them are still in suspension. Repetition, as directed, lessens this inaccuracy but does not eliminate it.

Still-water settling tube is an improvement on decantation. The apparatus (Fig. 105) consists of a glass tube of about 1.5-in. uniform inside diameter and 8 ft. long, converging in a 60° cone at the bottom to a stopcock with 1.5- to 2-mm. hole, and expanded at the top into a 60° funnel of about 200-cc. capacity. Calibrate the tube from stopcock to base of funnel sufficiently closely that the length at any part of the tube corresponding to a given volume withdrawn at the stopcock is known. From this calibration make a table of volumes for the required number of successive drafts such that the distance that the slowest settling particles are dropped, *i.e.*, that the surface originally at the base of the funnel drops, at each draft, is the same. Thus in Fig. 105, if the tube is calibrated for 10 draws, the successive volumes drawn should be such that the distances ab, $bc \cdots jk$, representing the successive drops of the surface originally at a, are equal. The charge, weighing from 20 to 50 gm., should be mixed with water to form a volume somewhat less than 200 cc. Place a closely fitting disk of metal or fine screen cloth at the base of the funnel with a handle extending above the rim. Charge the feed carefully and wash in the last part with a fine jet. Then, first observing and noting the time, remove the disk carefully to prevent the solid from plunging and allow settlement for a predetermined time, or for a time dependent upon the appearance or amount of material at the stopcock. The tube should be jarred slightly at intervals to prevent material from clinging to the sides. Draw off now the volume corresponding to the first equal drop in surface of settling column and set aside. Make successive draws at intervals determined by the requirements of the analysis, *e.g.*, at equal intervals, or at intervals determined by Fig. 104, or by Stokes' equation, to yield predetermined sizes, or at intervals which the settling behavior indicates will yield equal weights of solid. When the total volume of withdrawals is equal to the original volume of water in the settling column, there will remain a volume equal to that of the feed pulp and containing the finest slime. Remove this at one draw and class it as of slower settling rate than that of the slowest-settling particle in the preceding grade. Sizes of particles in the different grades may be determined by microscopic measurement or may be estimated from the known settling rates. Decant clear water from the different grades, dry at 110° C., cool, and weigh.

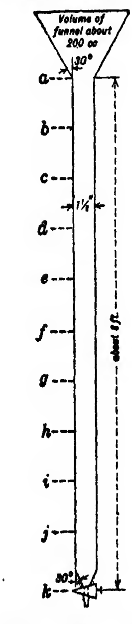

FIG. 105. Still-water settling tube.

If l is the total length of settling column, measured from neck of funnel to top of stopcock, N = the total number of draws, and n = the number of any given draw, then the average distance D_n that the particles taken in the nth draw have settled is given by the equation $D = l(2N - 2n + 1)/2N$. If t_n = the total time elapsed from the beginning of settlement until the end of the nth interval, the average settling velocity V_n of the solids collected during the nth interval is given by the equation $V_n = l(2N - 2n + 1)/2Nt_n$. If equal time intervals t are taken, this equation becomes $V_n = l(2N - 2n + 1)2Nnt$. The slowest-settling particle in the last grade settles through the distance $D_{ss} = l - l/N$ in the time t_n. Its settling velocity is, therefore, $V_{ss} = l(N - 1)/Nt_n$ and the most rapidly settling particle in the final draft has a slower velocity.

Elutriation by rising water currents is performed by subjecting the material to be graded to rising currents of different velocities and collecting separately the material lifted by each current.

Procedure. The apparatus shown in Fig. 106 (*32 M&M 125*) is one of the simplest of these devices. As described, it was used merely to separate slime from a sample that was to be screen sized subsequently. The procedure was to set the dial cock f so that the current at the overflow level was sufficient to carry over all slime, then to close the rubber tube g with a pinchcock, charge the weighed sample into a and thereupon release the pinchcock. When overflow was clear, the material in e and that remaining in the tube were collected and sized. The same apparatus may, however, be used to separate a number of different grades. There are two alternative methods of procedure, *viz.*: (1) To set the current at the lower part of constriction c to just prevent slime from settling, feed the sample into a and collect the overflow in a pail or tub. Then raise the current slightly, feed back the settled material collected in e and again collect the overflow, repeating this procedure until the desired number of grades has been made. (2) Set the current originally so that the velocity at the lower part of section c will permit only the coarsest material to settle. Collect overflow and settled product. Separate the slime from the sand in the overflow by decantation. Slack off the current slightly, feed back the sandy portion of the first overflow and again collect the settled material. Repeat with gradually slower

currents until as many grades as desired have been made. Final products will consist of the various settlings and the decanted portion of the first overflow. This apparatus is adapted for relatively coarse grading only.

Schoene apparatus (Fig. 107) is distinguished by the fact that overflow is made through a piezometer, which permits ready setting of current velocities, once the piezometer is calibrated to the tube with which it is to be used. In the figure, *a* and *b* are sorting tubes of smaller and greater diameter respectively for coarse and fine sizing. The procedure consists in first determining the average cross-section of the cylindrical portions of the tubes by weighing the water drawn through the stopcocks corresponding to the measured length between two marks delimiting the cylindrical section. Knowing the average cross-section from the determination, average rising-current velocities can be determined by weighing overflows collected for known times. This is done and at the same time the corresponding

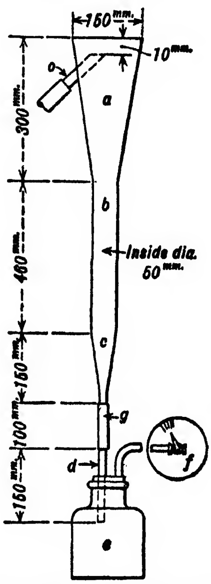

FIG. 106. Rising-current sizing tube.

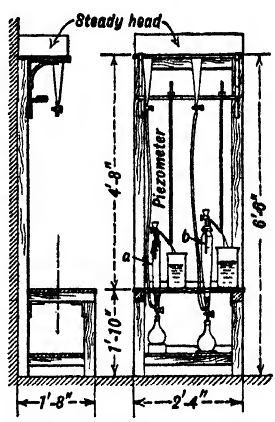

FIG. 107. Schoene elutriation apparatus (modified).

piezometer readings are taken and a curve showing average rising velocities in terms of piezometer readings plotted. To make a sizing analysis, fill the feed-water tank and maintain sufficient inlet so that the tank will overflow throughout the test. Close the stopcock at the lower end of the sorting tube and admit sufficient water from the tank so that the level in the sorting tube stands a couple of inches above the stopcock. Make up the weighed feed sample into a dilute pulp sufficiently small in volume to less than fill the tube and introduce this through the funnel. Close the funnel stopcock. Open the water cock slowly until the piezometer reading indicates the desired minimum current and continue this current until the discharge carries substantially no solids. Set aside the overflow, then increase the current and collect another grade and continue until all but the coarsest material is overflowed. Collect this last through the stopcock at the bottom of the sorting tube. Determine the size of material in different grades by microscopic methods or estimate from Fig. 104 or from Stokes' equation. Stadler (*22 IMM 686*) points out that, if the specific gravity of the material being sized is known, solid weights may be determined by weighing the material in a specific-gravity flask, or its equivalent, thereby saving much time in drying.

According to Schoene a calibration curve is unnecessary and the velocity V corresponding to any piezometer reading h may be obtained from the equation $V = V_1 \dfrac{h - c}{h_1 - c}$ when V_1 and h_1 are corresponding values from one observation and c is a factor, determined once for all, from the relation $c = (Q^2h_1 - Q_1^2h)/(Q^2 - Q_1^2)$ in which Q and Q_1 are quantities in cc. per sec. corresponding to piezometer readings h and h_1 respectively in cm.

Multi-tube elutriation. If a series of Schoene tubes of the type shown in Fig. 107, of different diameters, is set up without piezometers so that the overflow tube of the smallest enters the apex of the next larger, and so on, a charge of solid can be placed in the first and a current started of sufficient velocity to lift all but the coarsest material out of the first tube, and if the last tube is of sufficient diameter to overflow only the finest slime, there will be collected in the successive tubes successively finer grades, and the entire separation can be done at one operation. This is the best type of apparatus for routine tests, but it lacks flexibility. A homemade form is shown in Fig. 108 (*115 Aa 357*). PROCEDURE for 200-gm. charges comprised 24-hr. runs in which the charge was first rolled in a bottle for

several hours in a dispersing solution, wet-screened on a 200-m. sieve, the <200-m. material thickened by sedimentation, and then charged to the elutriator while the latter was full of water (clean, from a

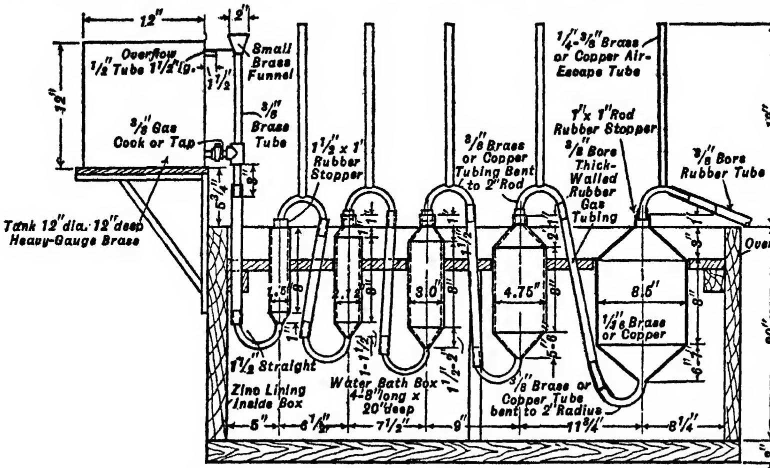

FIG. 108. MT. MORGAN multi-tube elutriator.

constant-head tank) and flowing at a low rate such that the charge volume plus the fresh water did not exceed the maximum flow calculated. Charging was done in three substantially equal fractions with 10-min. intervals between. When all charge was in, the rate was brought up to the calculated rate by two or three steps at 15-min. intervals. Overflow was collected in white-enameled pails. Tests were run for 24 hr. with occasional checks of flow rate. To discharge, current was shut off, about half an hour allowed for settlement of material in tubes, and this was then drawn off into enameled pails, the tubes were washed out, and the samples decanted and dried.

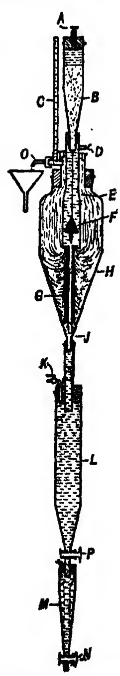

FIG. 109. Andrews kinetic elutriator.

Andrews kinetic elutriator, Fig. 109 (*40 MM 301*), comprises essentially free-settling elutriating chamber *H*, with valved overflow *O* carrying an indicating piezometer *C*, a feed tube *E* surmounted by a feed chamber *B*, a disintegrating ejector *G–F*, a hindered-settling column *L* for sand classification and a sand-collecting chamber *M*. In operation the sample is mixed thoroughly with the elutriating liquid, *e.g.*, water, in chamber *B* which, with air vent *A* closed, will hold the carrying liquid with the bottom open. *B* is then placed in position as shown and elutriating fluid (the same as used to charge *B*) is run in through *N* until overflow occurs at *O*. By opening *D* the level of introduced liquid rises until it merges into the liquid body in *B*, when solid settles in the stationary column in *E* (*D* being again closed) until, at the bottom of *E*, it meets a rising current through *G* and is flowed against the underside of *F*. This is supposed to effect disintegration of floccules by mechanical impact, and to impart to granular particles rebounding from *F* a downward velocity in excess of that due to gravity alone. Granular particles thereupon settle into *L* while finer particles rise through *H* and overflow at *O*.

Shiretts and Evans (*88 Aa 423*) report superior sizing with injector apparatus *G–F* in place. They also recommend certain changes in apparatus and operation, *viz.*: (1) A constant-head tank placed about 7 ft. above *N* in addition to the small constant-head tank supplied with the apparatus; this would tend to eliminate air. (2) Frequent inspection and lubrication (with vaseline) of the needle valves at *A* and *D* to prevent rusting. (3) Modification of the smaller "variable nozzle" at *O*. As supplied, this is 1.5-mm. diameter, and produces a rising velocity of 0.2 mm. per sec. in *H*; they recommend reduction to approximately 0.7 mm., giving a velocity in *H* of approximately 0.05 mm. per sec. (4) After removing as much overflow as desired, to drop the granular residue into *L* by closing *P* and opening *K*, whereupon separation of sand is effected by differential settlement into *M* by opening *P* and varying the water pressure at *N*. Continue this operation until fines rise into *H*, then holding them there by a pinchcock on the rubber tubing joining *L* and *H* until residues are drawn from *M*. Elutriated fractions should be sized microscopically. Mean diameters calculated as the arithmetic mean of the visible microscopic diameters showed reasonable agreement between supposed duplicate samples. Time for complete elutriation tests, making 6 fractions, was 14 to 15 hr.

U.S.B.M. elutriator (Fig. 110) is the present form of the device first described by Gross, Zimmerley, and Probert (*RI 2951*), improved on by Clemmer and Coghill (*129 J 551*), and further improved by Cooke (*RI 3333*). The elutriator column consists of a 60° brass cone *A*, having at its apex a 1/4-in.

hole that can be closed with a rubber stopper *H;* a glass cylinder *B*, 2 in. in height, and a brass top ring *C* fitted with a thin metal overflow rim and spout *J*. Located coaxially with the column is a stirrer comprising a glass tube *E*, to the lower end of which is cemented a cylindroconical brass bulb *I* (60° cones) carrying two perforated brass vanes *K* which clear the elutriator cone by 1 mm. Within the stirrer is glass tube *D* which extends from the bottom to about 2 in. above the level of the pulp overflow, its function being to prevent forcing of air bubbles into the material undergoing elutriation. Immediately above the stirrer is a culluloid grid *G* to prevent swirling of the pulp. Classification water is admitted to cone *A* through *E* via a small Vezin-sampler apparatus comprising a funnel on the upper end of *E*, rotating with it, a small trough extending beyond the rim of the funnel and leading into it, and a microspigot of drawn glass delivering outside the periphery of the funnel but intercepted by a trough, the fraction of the stream taken by the trough cutter depending upon its central angle. The spigot is fed from a small constant-level cone, fitted with an overflow pipe, fed in turn from a larger constant-head tank. Arrangement may be made to recirculate overflow.

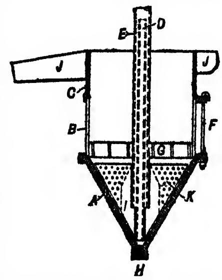

FIG. 110. U.S.B.M. elutriator.

Procedure. Material to be elutriated is first dispersed in distilled water by agitation, using a dispersing agent, if necessary. Extent of dispersion is determined by dark-field microscopic examination. The water-supply tank is filled with distilled water and sufficient dispersing agent to insure continuance of the dispersed condition during the removal of all sizes up to 6- or 10-μ. The supply-tank valve is opened and enough water is allowed to flow into the constant-level cone to insure a slight overflow into a recirculating tank. The smallest cutter is inserted in the feed cone and the stirrer is started. The small amount of water entering the elutriator prevents choking of the orifice at the bottom of the stirrer by coarse particles. Delivery of the spigot is checked and adjusted. Dispersed pulp is now added to the elutriator with enough water to bring the pulp level to within 1 in. of the overflow lip. Overflow is collected in enameled-iron pails. Products are allowed to settle, the supernatant liquid is siphoned off, and the residue is washed into pans, dried, and weighed. The finer sizes may require flocculation before settling can be effected; this may usually be done by the addition of 5 or 10 cc. of a 1% solution of aluminum sulphate. CAPACITY is 120 to 200 gm. of quartz divided into 6 fractions between 52- and 9.3-μ in 8 hr., or 10 fractions between 52- and 2.3-μ in less than 60 hr. Gaudin, Groh, and Henderson (*22 IEC 1363*) describe a modified form of this elutriator, wherein the stirrer is completely eliminated and the elutriator column is lengthened as in the earlier designs. As a consequence of these changes larger capacities are claimed, in apparent contradiction of Cooke's conclusion that capacity is increased by shortening the column.

Use of acetone as described by Gaudin *et al.* (*ibid.*) is an important improvement in elutriation technique. As a consequence of its lower density and viscosity, settling rates are higher, hence time required for a test is materially decreased. The chief drawback is the economic necessity for recovery.

Elutriator design. See p. 117.

14. ELUTRIATION WITH AIR

Sedimentation in air is governed by the same laws as sedimentation in liquids (see Sec. 6, Art. 1), but owing to the lower resistance of air to particle fall, and the less frequent occurrence of Brownian movement in air, separations therein are more rapid and tend to be sharper than in liquids. Likewise the finest product is available in uncemented form as made, while the finest product of water elutriation can never be obtained dry in a completely nonclotted state. Air elutriation is also applicable to substances like cement, plasters, and limes, which react with water to form new and different solid compounds.

Many different forms of apparatus have been used, ranging from the simple device shown in Fig. 111 to the complicated multiple-tube arrangement of Fig. 113.

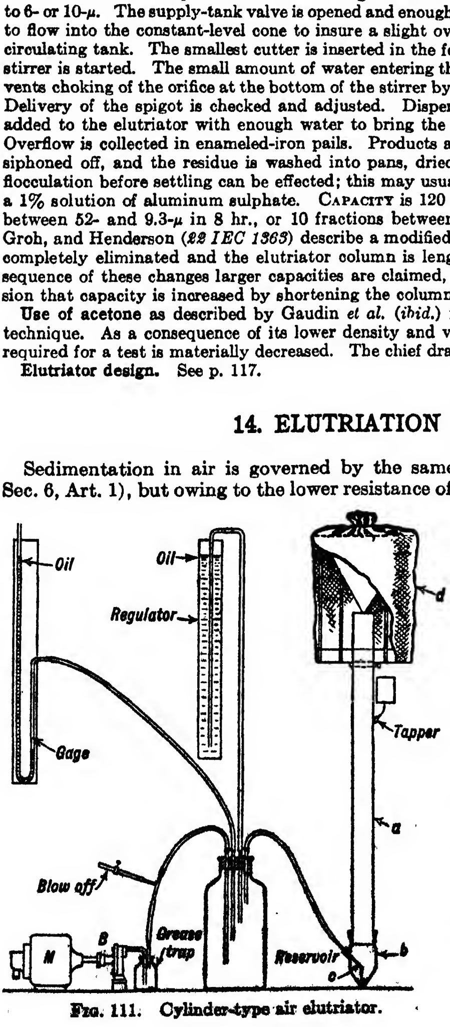

FIG. 111. Cylinder-type air elutriator.

Cylinder-type air elutriator, as developed by U. S. Bur. of Standards (*TP 48 USBS*) consists (Fig. 111) of a vertical cylindrical polished-brass sorting tube *a*, 2.7-in. inside diameter by 60 in. long, with a bulb *b* at the bottom for holding the sample, three nozzles *c*, 0.04-, 0.09- and 0.13-in. diameter, for vary-

ing the velocity of the entering air and hence the intensity of agitation in the bulb and the velocity of the rising air current in the sorting tube, and a collector d, about 10-in. diameter by 20 in. high, with canton-flannel covering, for receiving the various solid fractions while passing the air. Air is supplied at constant pressure (ordinarily about 1 lb. per sq. in.) from the reservoir, which is supplied by a motor-driven blower and controlled by a blow-off valve and an oil regulator. The latter is a vertical pipe about 4-in. diameter by 5 ft. long, closed at the bottom and nearly filled with kerosene. A long glass tube, open at the lower end and connected at the top with the reservoir, extends to a point within a short distance of the bottom of the oil-filled cylinder and the back pressure is adjusted by changing the depth of submersion by raising or lowering the tube. In operation the blower is run at a speed sufficient to maintain slightly more than 1 lb. per sq. in. pressure with a small amount of blow-off, and the regulator is then set by trial. The sample taken is <200-m. material, weighs 30 to 50 gm., and is divided into four fractions. The flow of air in the sorting stack is reasonably constant in velocity and uniform across the section; air delivery is not retarded by the sample, if the nozzle tip is kept 1 cm. or more above the surface, nor by the back pressure of the collector sack. The sample must be kept stirred up in the bulb, if operation is to be satisfactory. The dependent factors are air pressure in reservoir, diameters of nozzle, bulb, and stack, shape of bulb, and quantity of sample. Lodgment of material in the separating stack, which would hinder separation, is guarded against by polishing all interior surfaces, beveling the upper rim of the stack to a knife edge, tapping the stack continually during operation with an electric tapper, and so designing the collector that material once therein cannot again enter the sorting tube.

Operation is as follows: (1) With the nozzle that is to be used for the finest separation connected to the reservoir, but not in place in the bulb, start the blower and adjust the speed, blow-off, and oil regulator for a constant pressure of very slightly more than 1 lb. per sq. in. with the regulator blowing off a slight amount of excess air. Disconnect the nozzle, insert it in the bulb, and weigh the two to the nearest 0.01 gm. Add the sample to the bulb (33.33 gm. if the 0.04-in. nozzle is to be used for the finest separation, otherwise 50 gm.), attach to the stack, start the tapper, and connect the air tube. Continue elutriation until the loss per unit of time is at the rate of some predetermined amount (Pearson and Sligh have adopted 0.02 gm. per min.). The end point is determined by stopping blowing some 15 or 20 min. before the estimated time of completion, allowing 30 sec. to 1 min. for material to settle from the stack, then weighing the bulb and contents. Continue blowing 10 min. and again weigh. Repeat until the 10-min. loss is less than 0.2 gm. Interpolate for the weight at the minute when the loss was at the rate of 0.02 gm. per min. Repeat with 0.09-in. and 0.13-in. nozzles.

Actual sizes of the various grades for a given apparatus and material must be determined by microscopic measurement, but once determined, the sizes are reasonably constant for other samples of the same material in the same apparatus With cement, experiment shows that the average diameter reckoned as $D = \sqrt[3]{blt}$, where b, l, and t are the arithmetical means of a number of determinations of breadth, length, and thickness, respectively, of grains, checks very closely with the mean of b for both the air-elutriated grades and the material on 100- and 200-m. sieves. Results of one determination are shown in Table 34.

Shape of bulb is not important except in so far as it determines the amount of material that can be treated with the minimum air stream. Diameter of nozzles need be neither accurately specified nor determined. Diameter of stack should be the least that is consistent with the finest separation, *i.e.*, the least that will give sufficiently low air velocity in the stack when the material in the bulb is properly permeated. At this, the agitation in the bulb when sufficient air is rising in the stack for the coarsest separation will be great. Length of stack has been tested over the range from 5 to 8 ft. and results with the short stack shown to be reasonably concordant with those of the long stack. Abrasion is negligible under conditions of minimum stack diameter. Atmospheric conditions have inconsiderable effects. Small variations in pressure (less than 10% range) may be neglected. Size of sample may range between 25 and 50 gm. without noticeable effect on results.

Table 34. Comparison of average diameter with mean breadth of air-elutriated and screened particles (*after Pearson and Sligh*)

Grade	Mean breadth, b, inch	Average diameter, $\sqrt[3]{lbt}$, inch
Rising with 0.04-in. nozzle...	0.00062	0.00066
Rising with 0.09-in. nozzle...	0.00130	0.00129
Rising with 0.13-in. nozzle...	0.00181	0.00178
Not rising with 0.13-in. nozzle but <200-m.	0.00368	0.00371
100~200-m.	0.00703	0.00690

Dynamic air analyzer, described by Roller (*TP 490 USBM*), is shown in Fig. 112. Separating column a consists of a brass cylinder 9 in. (or 4 1/2, 2 1/4, or 1/8 in.) in diameter and 2 ft. long, reduced at the top to join a 2-in. brass collar, and at the bottom to join a 1-in. brass tube. The 2-in. collar is fitted with a rubber stopper which carries a 3/8-in. copper U-tube, to the end of which a paper thimble b is attached by means of another rubber stopper. Attached to the 1-in. tube by means of stout red-rubber tubing is a copper U-tube c of 1-in. internal diameter and about 4-in. radius of curvature. Fitted concentrically within this tube and secured thereto by means of a rubber stopper is a tapered glass tube d, the tip of which is about 30° off the center line of the U-tube c. A series of such tubes with tip diameters ranging from 1- to 5-mm. is required. The left arm of U-tube c is attached to a spring e by means of a brass collar, also carrying a back-stop lug f which limits the amplitude of the vibration imparted to the U-tube by the hammer g. All joints and seams in the separator are locked and soldered, and the interior of the separator is preferably gold-plated. Grounding of the U-tubes and separator is said to reduce adherence of material to the walls. Air-supply system consists of a rotary compressor h, capable of delivering 1 c.f.m. at a pressure of 15 in. of mercury; a reservoir i fitted with

blow-off valve j and a mercury manometer for measuring delivery pressure, a drying bottle k containing a 50–50 volumetric mixture of sulphuric acid and water, and a capillary flow meter l.

FRACTIONATION END POINT adopted by Roller is a rate of loss of 0.1 to 0.2 gm. per hr. With this end point a fractionation usually requires 3 to 6 hr. and a run of five complete fractionations, 24 to 36 hr., for a 25-gm. charge. To operate the elutriator, a 25-gm. charge is dried at 100° C. for an hour, then placed in U-tube, the proper nozzle (of such tip diameter as will give a rate of fractionation of 9 gm. per hr. in the first half hour on the 10-μ fraction, or a higher rate if hardness of the material exceeds 2) is introduced with the tip slightly under the surface of the sample, and the air flow is adjusted to the desired rate by means of stopcock m and two-way cock n. Elutriation is continued to the end point, when the material in the dust-collecting thimble is removed. The separator tube is then changed and the process is repeated to get the next coarsest fraction. Repetition with different tubes and nozzles yields the different products.

Quality of separation may be gaged by the amount of overlap in sizes between adjacent grades. Table 35 shows results of a microscopic analysis of products from a sample of Portland cement. Overlap was 15 to 20% at the coarse end (more in the 5~10-μ fraction) and 3 to 5% at the fine end in most fractions, reckoning nominal limits on Stokes' law, and assuming uniform density.

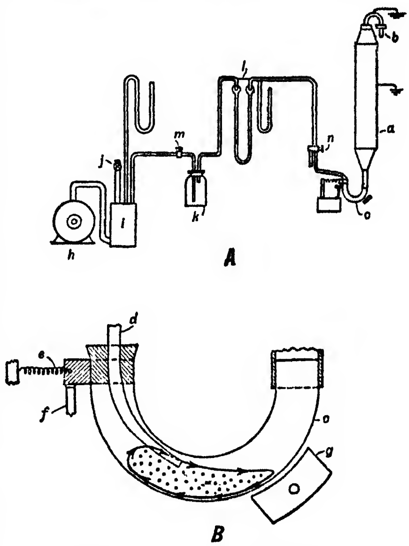

FIG. 112. Dynamic air analyzer.

Infrasizer (Haultain, *40 CIMM 229*) is a multitube air elutriator wherein air-borne particles impinge on a ball (of aluminum, steel, marble, or a golf or ping-pong ball) and pass in a thin high-velocity stream between ball and rubber seat (item a, Fig. 113) into conical elutriation tubes (Hollinger-type; tubes of older Lake Shore-type are shaped as in Fig. 112). The elutriation tubes, stainless steel cones of varying angle, of maximum diameters ranging between 2 1/2 in. and 14 in., and length between 2 1/2 and 4 1/2 ft., are series connected by rubber tubing; the

Table 35. Distribution of particle diameters in the various fractions of Portland cement elutriated in the Dynamic elutriator (*after Roller*) [a]

Nominal size, μ	Particle diameters, μ	Number, %	Weight, %
0~5	<1	77.2	4.8

[a] Particles counted were 850 for the 0~5-μ fraction and 45 for each of the other fractions.

inlet of the cone of smallest diameter is connected to the air supply and the outlet of the largest cone to a dust-collecting bag. Cones and tubing should be grounded to minimize adherence of particles to walls due to electrification; vibration of the cones ($^3/_8$-in. amplitude at 60 s.p.m.) is directed toward the same end. Volume of air supplied to Infrasizer is determined by an orifice in a diaphragm with a differential water manometer tapped in on the high and low sides of the orifice. In normal use a pressure difference of 20 in. water is maintained. A mercury manometer is tapped in on the pressure side to give air pressures (usually 10 in. Hg). Back pressure of 20 to 30 in. water, determined by a manometer, varies with the fineness of the sample and the number of cones in use. If the dust-collecting bag becomes clogged, back pressure increasesand mayblow out manometer; on the other hand, no back pressure can be maintained if leaks exist in the elutriator system.

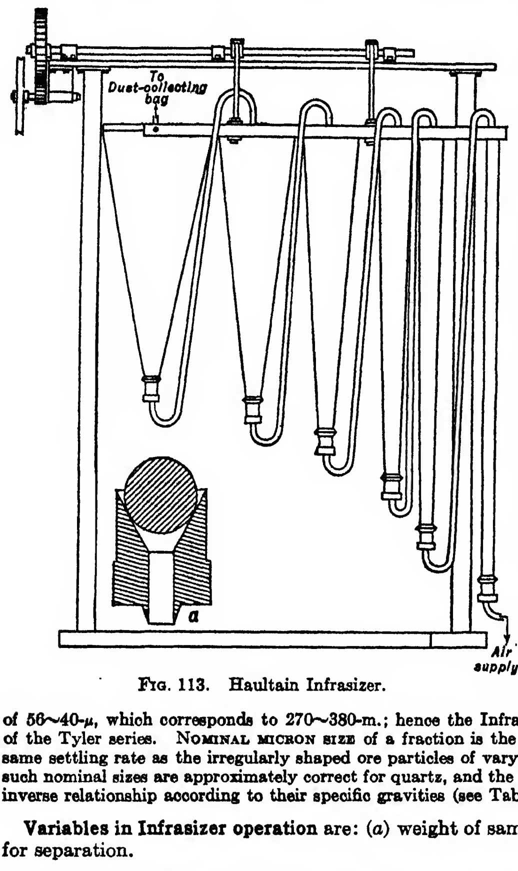

FIG. 113. Haultain Infrasizer.

By using cone diameters which vary as $\sqrt{2}:1$, the average particle diameters of successive products decrease by the ratio $1/\sqrt{2}$. At LAKE SHORE (*29 CIMM 279*) the coarsest fraction had nominal limits of 56∼40-μ, which corresponds to 270∼380-m.; hence the Infrasizer gives a fairly close continuation of the Tyler series. NOMINAL MICRON SIZE of a fraction is the diameter of glass spheres having the same settling rate as the irregularly shaped ore particles of varying specific gravity. At LAKE SHORE such nominal sizes are approximately correct for quartz, and the sizes of heavier particles bear a rough inverse relationship according to their specific gravities (see Table 36).

Variables in Infrasizer operation are: (*a*) weight of sample, (*b*) air flow, (*c*) time allowed for separation.

Weight. Samples ranging from 50 to 1,000 gm. have been elutriated successfully, but if a particular fraction is unduly large, a condition known as CROWDING (similar to screen crowding) may exist, and the sample weight must be adjusted to eliminate it. If the sample weight is too small, say 100 gm. or less, the three fine fractions of some materials hold up and do not elutriate properly.

Air flow, as indicated by the differential manometer, determines the velocity within the separators, and hence controls the nominal limits of the fractions. It must therefore be standardized.

Running time depends upon the size of the sample, the degree of separation desired, and the nature of the material. At LAKE SHORE, tests were run until the rate of change of the >28-μ and the <10-μ material did not exceed 0.5% with a 15% increase in time. The running time, to this end point, varies directly as the weight of the sample, and can be approximated by the equation $t = (W + c)/c$, where t = time in hr., W = weight of sample in gm., and c is a constant which varies with the material and its previous history. For samples weighing 400 and 800 gm. the respective times were 3 1/2 and 6 hr.

Table 36. Variation of particle size with specific gravity in Infrasizer products at Lake Shore

Nominal quartz size	Relative sizes in microns		
	Pyrite	Telluride	Gold
<10	<8	<6 1/2	<5
10 to 14	8 to 11 1/2	6 1/2 to 9 1/2	5 to 7
14 to 20	11 1/2 to 16	9 1/2 to 13	7 to 10
20 to 28	16 to 23	13 to 19	10 to 14
28 to 40	23 to 32	19 to 26	14 to 20
40 to 56	32 to 46	26 to 38	20 to 28

Routine testing. When only two sub-sieve fractions are required, the Infrasizer may be run as a single-tube elutriator by removing all cones save one. Using only the 5-in. cone, Haultain (*ibid.*) re-

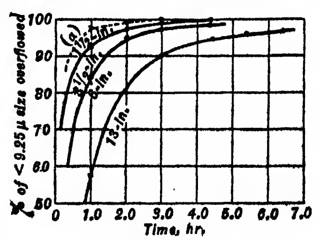
ports a running time of 30 min. for 20-gm. samples of MACASSA tailing. REPRODUCIBILITY was excellent; for eleven consecutive runs the weight in grams of the $>28\text{-}\mu$ material was 5.54 ± 0.02.

Elutriator design seeks (1) complete dispersion of the sample in the fluid, (2) constant fluid velocities with a plane velocity front through the various separator tubes, (3) short treatment time for a given weight of sample, while maintaining high quality of separation, (4) good separation as measured by the extent of overlap between grades, (5) production of grades of nominal sizes that continue the Tyler standard sieve scale, (6) minimum attrition.

Dispersion is of utmost importance in fine separations but relatively unimportant in making the coarser fractions. The tendency of the smallest particles to adhere to larger particles and to each other is overcome in water elutriators by the use of a dispersing agent; saponin, sodium silicate, sodium hydroxide, ammonium hydroxide, agar agar, gum arabic, glue, tannic acid, etc., have been used. See also Sec. 12, Arts. 7, 8, 10, 42, and Sec. 15, Art. 3. Adhesion of particles to the walls of the elutriator is rare with glass; with metal, adhesion has been reported and is probably due to an interaction between the metal (or surface products thereof) and the particles. Metal elutriator parts may also affect dispersion by reason of interaction products with the elutriator fluid. The adverse effect of galvanized iron and zinc is reported by Cooke (*loc. cit.*), who recommends the use of Allegheny metal. Water containing unknown dissolved salts is always suspect; distilled water is preferable. In air elutriators dispersion is achieved mechanically by impinging a high-velocity air jet on the sample, as in the cylinder and dynamic elutriators, or by forcing the sample through a high-velocity jet, as in the Infrasizer. The shearing action thus obtained breaks up agglomerates. Adhesion of particles to walls is decreased by grounding the tubes to eliminate electrostatic attraction, and by vibrating to jar material loose.

Constant fluid velocities are necessary because fluctuations increase overlap between grades. Flow meters, preferably of recording type, should be employed. Capillary flow meters for water clog easily. Introduction of the charge is usually accompanied by a back pressure which changes during the run, and between runs for single-tube elutriators. Correction of this back pressure is necessary, if accurate sizing is desired. A parabolic velocity front may vary from zero at the walls to approximately twice average at the center; such a front is probably responsible for most of the overlap at the coarse end of the various fractions. Attainment of a plane velocity front in separator tubes is probably impossible. Stream-line flow is attained by a length : diameter ratio $> 10 : 1$. Neither is necessary for precision sizing.

Sample size. If further testing, *e.g.*, assaying, of elutriator products is contemplated, it may be necessary to elutriate samples weighing 300 to 1,000 gm. If elutriator capacity is too small but the elutriator gives reproducible results, the sample may be split into a number of smaller samples and the products combined, but the time element is then prohibitive. The structural factors determining allowable sample weight in one run are not well understood. In general, for water elutriators, an increase in diameter of the separating column permits use of larger charges. If stream-line flow is desired, increase in diameter should be accompanied by increase in length. Cooke has demonstrated that length may be decreased without affecting separation adversely. In air elutriators of the cylinder and dynamic types (Figs. 111, 112) the weight of charge is determined by the size of the bottom roughing elements. If these are increased in size, air volume must be increased to maintain minimum suspending velocities (Sec. 9, Eqs. 14, 15, 16); hence stack diameter must be increased to produce same nominal size. With the Infrasizer, an increase in the diameter of the cylindrical portion of the rubber plug, with consequent increases in length and diameter of the cones, will probably increase permissible sample weights.



a Theoretical.

FIG. 114. Length of column *vs.* time for elutriation.

Time for elutriation of a given sample weight to a fixed end point may be shortened by series connecting elutriator tubes of proper dimensions. The structural factors affecting elutriation time in single-tube elutriators are practically unknown. Cooke (Fig. 114) shows that shortening the column decreases elutriation time.

Quality of the separation depends upon the elutriation time, end point, constancy of fluid flow, completeness of dispersion, and the nature of the velocity front in the separator tubes. Elutriation rate (Fig. 114) decreases sharply at first, then more gradually until it finally becomes almost constant. The chosen end point should lie on that portion of the curve which is substantially parallel to the time axis. Samples of different weight elutriated for a time sufficient to reach this end point will probably yield grades of equal quality. It is impossible to compare results with different elutriators or with the same elutriator on the basis of published data because these, with few exceptions, are not in a form that permits calculation of overlap. OVERLAP should be stated. A suitable standard material should be adopted for use in CALIBRATION. Different END-POINTS should be adapted for rough work, for precision sizing, and for routine testing.

Size scale. Production of grades whose nominal size decreases by $1/\sqrt{2}$ is relatively easy. For single-tube elutriators fluid velocity is adjusted to give the desired grade for an elutriator tube of given diameter, and thereafter velocity is decreased or increased by a factor of $1/2$ or 2 respectively. For multi-tube elutriators the diameters of successive tubes increase in the ratio of $\sqrt{2} : 1$ and the diameter of the smallest tube is chosen so that its lower nominal limit is approximately $52\text{-}\mu$. Under these circumstances velocities in successive tubes decrease by one-half, hence nominal sizes decrease by $1/\sqrt{2}$.

Attrition is nonexistent in water elutriators without stirrers. The stirrer in the apparatus of Fig. 110 was shown in tests with quartz, tripoli, and galena not to produce fines. Similar tests on the dynamic elutriator (Fig. 112) and the Infrasizer indicated lack of attrition.

15. MICROSCOPIC SIZING

Microscopic sizing is the only method which measures particles by direct comparison with a scale. This makes it an excellent check on other methods of sizing. Measurement may have for its object either (*a*) allocation of particles to size fractions according to the magnitude of one or more of the particle dimensions, or (*b*) determination of a linear dimension of a particle or particles.

Accuracy depends upon the nature and quality of the optical equipment and the mount, and upon the method of measurement. Other things being equal, accuracy of linear microscopic measurements is relatively unimportant in item *a* above, provided elementary rules are obeyed to insure good image formation, since allocation of particle to a particular size fraction is accomplished by comparison with the image of a ruler grid focused in the plane of the object or in a plane conjugate therewith. In case *b* accuracy of the linear measurement depends upon the mechanical accuracy in the instrument and upon optical limits controlling the fineness of the image. The width of the outlines in an image depends primarily upon the resolution and secondarily upon the focus, the illumination, and upon the relative indices of refraction of material and mount. The limit of width of the outlines is approximately equal to the resolving power. For axial illumination using an objective of 1.40 N.A. the limit is approximately ± 0.25-μ. This leads to an inescapable error of about 2.5% if the particle dimension is 10-μ and the error increases as particle size decreases. This fundamental fact is too often overlooked. Although accuracy of linear measurements can be improved by averaging repeated measurements of the same dimension, or by using oblique illumination, these expedients are rarely used. With the advent of the electron microscope with a limit of resolution of 0.005-μ, measurement of particle dimensions of, say, 0.1-μ with a precision of 2 to 5% is possible.

Optical system for accurate measurement should produce an image that is flat to the edges of the field, and is as free from spherical and chromatic aberrations as it is possible to attain. Any good high-power microscope (Art. 9) fulfils these requirements. It should be equipped with binocular vision, apochromatic objectives, and compensating oculars of the flat-field type. A petrographic microscope has the additional advantage of identification under crossed nicols.

Mounting (*ASTM E 20-33T*): (1) Particles shall be essentially in one plane. (2) Particles shall be free from motion. (3) Particles shall be dispersed, showing individual grains instead of aggregates and floccules. (4) Particles shall not be ground in mounting. (5) The mount shall be truly representative of the distribution of sizes in the material. The method of mounting is so closely dependent upon the physical and chemical properties of the sample that no technique universally applicable can be given. In general, however, procedure involves mechanical or chemical dispersion of the sample in a solution of a fixing agent and a volatile solvent. After evaporation of the solvent the fixing agent cements the particles to the slide. Dunn (*2 IECA 15*) used balsam in xylol, Green (*16 IEC 667*) used dammas in turpentine, Gehman and Morris (*4 IECA 157*) used rubber cement, Cooke (*RI 3333*) used gelatin in water. Other mounting media suggested are 0.5% glycerol in alcohol, styrax in xylol, the chlorinated naphthalenes, and saponin.

Detailed procedure (after Weigel, *TP 296 USBM*): Slides should be about 50×75 mm. Dilute the sample in a test tube with distilled water until it appears cloudy or very slightly milky on shaking. A drop or two of ammonia aids dispersion with clays. Pour off until the tube is about one-third full, agitate by blowing through a pipette, then quickly transfer a few drops to the slide, covering an area about 20-mm. diameter. Dry in an air bath at 105° C. Particles should be spaced with little or no overlapping and no flocculation. New slides should be prepared until this condition obtains. The slide may be used uncovered for work with 4-mm. and longer objectives and these should, therefore, be corrected for use without a cover glass. For the finest material (1-μ or less) an oil-immersion lens must be used and the slide must be mounted with a cover glass. Glycerine (index refr. = 1.47) is satisfactory for most nonmetallic minerals. Methylene iodide (index refr. = 1.74) is used for clays and talcs, if necessary, but it produces diffraction rings. To mount, place a drop of the mounting liquid on the center of the dried sample, drop the cover (35×50 mm.) into place and work it down with slight pressure and a rotary motion. Remove excess liquid with a filter or blotting paper, then run a ring of melted paraffin around the edge, using a fine camel's-hair brush. An excess of mounting liquid may result in washing fine material from under the edges of the cover and ruining the slide. If the sample is predominantly <6-μ it is used directly; if the distribution range is greater than this, rough separation by elutriation into 4 to 5 fractions is recommended.

Observation

Direct observation may be made with a Filar micrometer (*TP 48 USBS*), a co-ordinate-ruled eyepiece micrometer (Weigel, *loc. cit.*), or a co-ordinate-ruled scale, an image of which is formed in the object plane by the substage condenser (Ives, *154 JFI 73*). The last method permits binocular vision and the use of any desired combination of objective

and ocular without altering the relative magnification of scale and object, since the image of the scale is formed in the object plane. The eyepiece micrometer may conveniently be ruled with 6 or 8 squares on a side of the inscribed square of the field and with one of the larger squares subdivided. The sizes of most particles can be estimated from the large open square, but the subdivided square can be used, if necessary, to measure the smallest particles.

Manipulation. Set the sample slide so that the field is in one corner. Have the microscope fitted with lowest-power objective. Search the field for the largest particle, estimate the mean of the two principal dimensions exposed to the nearest 5-μ, then, beginning at one corner of the inner square, work over all squares in order, counting and recording the number of particles within this range. Repeat this process with successive fields until the whole slide is worked over, making as many counts as seem necessary to obtain a fair average of the grains per field. Repeat with the higher-powered objectives, narrowing the range of sizes each time, and counting fewer squares per field but the same number of fields as with the first objective. The range of the 16-mm. objective with 10× ocular (100 diam.) is convenient down to 30-μ; the 8-mm. objective (200 diam.) from 30- to 10-μ; the 4-mm. (430 diam.) from 10- to 1-μ; and the 1.9-mm. oil-immersion lens (950 diam.) for <1-μ materials.

Check on the relation of counts with different objectives was obtained by Weigel by re-counting the smaller size with an objective with the next higher power and reducing the results to equivalent areas. Eighty fields were counted with the 16-mm. objective, 40 with the 8-mm., and 20 each with the 4-mm. and 1.9-mm. The more uniform in size the material counted, the smaller the number of fields necessary.

When the slide is representative of a long-range sample, the procedure is the same, except that more fields and more squares per field must be counted on each slide, yet the total microscopic work is less than when elutriation is practiced. The time for a total-sample measurement including calculation is 5 to 6 hr. An elutriation test requires about 3 days, and the count and calculation one day more. Less skill and experience are needed for an elutriation test.

Projection of the image upon a ruled screen has the advantages that (*a*) it permits greater magnification than direct observation, and (*b*) it allows focusing through the

FIG. 115. Record of count of photomicrograph (*after Green*).

depth of the mount, insuring proper focus and count of all particles. Projection at right angles to the axis of the instrument is achieved by means of a mirror or a right-angle prism situated above the ocular; projection along the instrument axis is effected by the same objective and ocular that are used in visual work by adjusting the focus of the objec-

tive to form a primary image outside the focal plane of the ocular. Projection requires an intense source of illumination; an arc light equipped with condensers and cooling cell is admirably suited to the purpose.

Photomicrographic method (*Green, 192 JFI 637*) involves photographing the microscopic image and subsequently measuring the particles from a print or a projection of the negative on a screen. It has the decided advantage of making a permanent record. It also enables visual comparison of two or more samples. Particular attention must be paid to the mount so that all particles are in one plane.

Green's technique is to place about 1 mg. of the material on the center of the slide and cover with a drop of redistilled turpentine. Rub out with a straight, smooth glass rod, stroking lengthwise of the slide. Continue rubbing until the mixture is thick enough to prevent particles from floating and flocculating but thin enough not to streak, then stop with a slight lift on the last stroke to leave a wedge-shaped deposit and to yield fields of different intensities from which to choose the one for photographing. Evaporate the turpentine completely on a hot plate at a temperature that completes the drying in 40 to 50 sec. Mount with glycerine as described by Weigel (p. 118). Silverman and Franklin (*24 J. Ind. Hyg. & Tox. 51*) claim that such treatment causes comminution of the sample.

The photograph is taken with transmitted light that is absolutely axial. Fine-grained contrast plates are easiest to handle, but panchromatic plates give better detail. The important point in photography is sharp definition of particle edges. The negative should show 200 to 250 particles. Measurement is made by projecting on a screen so that the total magnification is 20,000 to 25,000 diam. and measuring with a millimeter rule to the nearest whole millimeter. Fig. 115 shows a form of record and calculation.

16. SIZING BY SEDIMENTATION

Sedimentation methods for the determination of size distribution may be classified according to the variable measured as follows: (*a*) measurements of the variation of density, (*b*) measurements of the variation of hydrostatic pressure, (*c*) measurements of the change in weight of an immersed body, and (*d*) measurements of weight of sediment deposited.

Principles. The theory underlying all of these methods is the same (see Oden *et al.*, *36 #3, 4 Proc. Roy. Soc. Edin. 219; 44 Proc. Roy. Soc. Edin. 98*), and is predicated on the fulfillment of the following physical requirements: (1) complete dispersion of particles while under test, (2) uniform distribution of particles throughout the liquid at the beginning of the test, (3) maintenance of constant temperature during test, so that no convection currents occur during sedimentation, and (4) a concentration so dilute that particles do not interfere with one another during their fall through the liquid, and that the density of the suspension never varies greatly from that of the liquid.

Density of a suspension at the beginning of a sedimentation test is given by

$$G = G_l + W_s(G_s - G_l)/G_l \tag{39}$$

where G = density of suspension, G_l = density of liquid, G_s = density of solid, and W_s = weight of solid per unit volume of suspension. At some later time t and some level x units below the surface, the density $G_{(x,\,t)}$ will have changed since some of the material in suspension has settled; particles with velocity $v > x/t$ will have settled below the level x, whereas particles with velocity $v < x/t$ will remain in the same concentration as at the beginning. If f denotes the fractional weight of particles which fall with a velocity less than v, there will remain fW_s grams of particles per cc. of suspension, hence

$$G(x, t) = G_l + fW_s\left(\frac{G_s - G_l}{G_s}\right) = G_l + fc \tag{40}$$

where $c = W_s(G_s - G_l)/G_s$ is a constant under fixed experimental conditions. When the fractional weight of particles having settling velocities between v_1 and v_2 is a desideratum of the test, it is customary to use the rate of change of f with respect to v, *i.e.*, $V = df/dv$, when Eq. 40 becomes

$$G(x, t) = G_l + c\int_0^V V\,dv \tag{41}$$

since

$$\int_{V_1}^{V_2} V\,dv = \int_{v_1}^{v_2} \frac{df}{dv}\,dv = \int_{v_1}^{v_2} df = f_{v_2} - f_{v_1}$$

When a distribution curve is drawn with reference to ordinate V and abscissa v, the area under the curve represents f. If the required range of v is too large, it may be necessary to condense this coordinate by the use of $\ln v$; then the ordinate is changed to vV in order that the area under the curve shall still represent f, *i.e.*,

$$X = \ln v \qquad Y = vV \tag{42}$$

In place of falling velocity v, equivalent radii or diameters may be used as abscissae. EQUIVALENT RADIUS is obtained by solving Stokes' law for the radius of a sphere having the same density and rate of fall as the material under test, *i.e.*,

$$a = k\sqrt{v} \quad \text{where } k = \sqrt{\frac{9b}{2g(G_s - G_l)}}$$

and b is the viscosity of the fluid. The co-ordinates of the distribution curve become

$$X = \ln \frac{a^2}{k^2} \qquad X = 2 \ln a - 2 \ln k$$
$$V = 1/2 \frac{k^2}{a} U \qquad Y = 1/2\, a\, U \tag{43}$$

where $U = \dfrac{df}{da}$.

Measurements of variation of density:
From Eq. 40

$$dG = c\left(\frac{\delta f}{\delta x} dx + \frac{\delta f}{\delta t} dt\right)$$

Case I: Densities at various depths are measured simultaneously; then $dt = 0$ and

$$\frac{\delta G}{\delta x} = c\frac{\delta f}{\delta x} = c\frac{\delta f}{\delta v}\frac{\delta v}{\delta x} = \frac{c}{t}\frac{\delta f}{\delta v} = \frac{c}{t} V$$

Therefore

$$X = \ln v \qquad Y = vV = \frac{x}{c}\frac{\delta G}{\delta x} \tag{44}$$

Case II: Density is measured at different times at the same depth; then $dx = 0$ and

$$\frac{\delta G}{\delta t} = c\frac{\delta f}{\delta t} = c\frac{\delta f}{\delta v}\frac{\delta v}{\delta t} = -\frac{cx}{t^2} V$$

Hence

$$X = \ln v \qquad Y = -\frac{t}{c}\frac{\delta G}{\delta t} \tag{45}$$

Measurements of variation of hydrostatic pressure.
Let $p(x, t)$ denote hydrostatic pressure at a depth x at any time t, then

$$\int_0^x G(x,t)\, dx = p(x,t) \quad \text{or} \quad \frac{dp}{dx} = G \tag{46}$$

Case I: Hydrostatic pressure is simultaneously determined at different depths, then

$$\frac{\delta G}{\delta x} = \frac{\delta^2 p}{\delta x^2} = \frac{c}{t} V \quad \text{or} \quad V = \frac{t}{c}\frac{\delta^2 p}{\delta x^2}$$

Hence

$$X = \ln v \qquad Y = \frac{x}{c}\frac{\delta p^2}{\delta x^2} \tag{47}$$

Case II: Hydrostatic pressure is measured at the same depth at different times. By partial differentiation of Eq. 46 (neglecting infinitesimals of higher order) it can be shown that

$$\frac{\delta^2 p}{\delta t^2} = -v\frac{\delta G}{\delta t} = \frac{cv^2}{t} V$$

Hence

$$X = \ln v \qquad Y = \frac{t^2}{cx}\frac{\delta^2 p}{\delta t^2} \tag{48}$$

Measurement of change in weight of an immersed body. Let W_a = weight of body in air, W_s = weight required to counterpoise body in partly submerged condition, and A_p = cross-sectional area of body.

Then $W_s = W_a - A_p p$. Hence

$$\frac{\delta W_s}{\delta t} = -A_p\frac{\delta p}{\delta t}$$

and

$$\frac{\delta^2 W_s}{\delta t^2} = -A_p\frac{\delta^2 p}{\delta t^2}$$

And the co-ordinates become

$$X = \ln v \qquad Y = -\frac{ct^2}{A_p x}\frac{\delta^2 W_s}{\delta t^2} \tag{49}$$

Measurement of weight of deposited sediment. For most practical problems the co-ordinate equations may be written as

$$X = \ln v \qquad Y = -\frac{t^2}{W_{s,\infty}} \cdot \frac{\delta^2 W_s}{\delta t^2} \tag{50}$$

These equations are approximations, justified only when the density of the suspension never differs appreciably from the density of the suspending liquid; otherwise a correction is necessary because the

weight of the deposit on the pan is determined in suspension and not in pure liquid. (For the derivation and discussion of correction see *19 Soil Science 9.*)

These sedimentation equations form the basis of a number of experimental procedures designed to determine the distribution curve.

Pipette methods for determining size-distribution curves measure the variation in density at a fixed depth within the suspension at different times or at a variable depth at different times. Illustrative of the former are methods described by Olmstead *et al.* (*TB 170, U. S. Dept. Agr.*) and Keen (*Physical Properties of the Soil,* Longmans, Green); Eqs. 45 are directly applicable for the interpretation of the results. Andreasen's pipette method is an example of the latter.

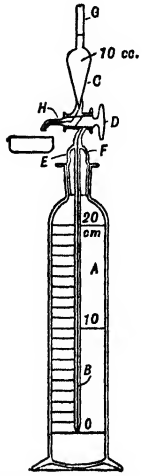

FIG. 116. Andreasen pipette.

Andreasen pipette (*19 Z 698; 20 Angew. Chem. 283*) consists of a graduated cylindrical flask *A* (Fig. 116) and a pipette *B* connected to a 10-cc. reservoir *C* by means of a three-way stopcock *D*. The ground glass stopper *E* has a small opening *F* permitting influx of air into the sedimentation flask when samples are withdrawn. The tip of the pipette is in the plane of the zero mark when the ground-glass stopper is properly seated.

Method of operation. A 3 to 5% suspension of the sample, properly dispersed in the sedimentation fluid, is added to the flask. The pipette is introduced and cylinder and contents are placed in a constant-temperature bath and allowed to come to equilibrium; when the apparatus is removed, a finger is placed over hole *F* and the suspension is agitated by inversion. When agitation ceases, a timer is started and the apparatus is returned to the bath. After given intervals of time, a sample is withdrawn by putting the pipette into connection with the reservoir by means of stopcock *D* and applying steady suction at *G* until a 10-cc. portion is withdrawn. This should not take more than 0.5 min. The new level of the suspension is noted and recorded. The sample is removed through *H* and analyzed for solid content.

Calculation. If c_o = concentration of original suspension and c_t = concentration of suspension at level h at time t (as determined by analysis) then c_t/c_o = fraction of the original quantity of material having a particle size smaller than the size corresponding to a falling velocity h/t, since all larger sizes will have fallen below the tip while the concentration of smaller sizes is unaltered. Table 37 shows the results of a sedimentation test. Column 3 gives the distance of the pipette tip from the suspension level in cm., column 4 gives the equivalent diameter in microns calculated from

$$D = 141 \left(\frac{hb}{t(G_s - G_l)}\right)^{1/2} \tag{51}$$

where D is in μ, h in cm., b in poises, and t in min. Columns 5, 6, and 7 give per cent. passing an aperture of the corresponding equivalent diameter for three runs on the same material. REPRODUCIBILITY appears to be good.

Time required for pipette testing depends upon the number of readings taken and upon the lower limit of the sizing; it may vary from 1 or 2 days for sizing to 10-μ to 7 or 8 days for sizing to a fraction of a micron. The SIZE RANGE that can be covered by this pipette method depends upon the viscosity of the sedimentation fluid; glycerine may be used to cover the range from 300- to 3-μ, ethylene glycol from 100- to 1-μ, and water from 30- to 0.3-μ.

Pressure-change methods, designed to measure pressures at different points within the sedimentation tube at the same time, have not proved successful because of experimental difficulties. On the other hand, methods based upon the measurement of pressure changes with time at a given point in the tube have been fairly successful. The original apparatus devised by Wiegner (*91 LVS 41*) consists of a cylindrical sedimentation tube of fairly large diameter, to which is attached a tube of smaller diameter which acts as a manometer. The manometer is parallel to the sedimentation tube and is provided with a stopcock near the point of connection. In operation the manometric tube is filled with sedimentation fluid, free of suspended particles, to the level of the suspension

in the sedimentation tube. When the stopcock is opened, liquid level in the manometer first rises then falls as sedimentation progresses. Since the pressure changes are small, ACCURACY is poor. Subsequent changes in design were prompted in the attempt to increase the sensitivity of the manometer. Improvements were made by Ostwald (*30 Koll. Ztschr. 62*), Zunker (*58 Landw. Jahrb. 159*), Goodhue and Smith (*8 IECA 469*) and others.

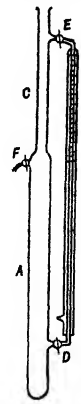

FIG. 117. Goodhue and Smith sedimentation tube.

Goodhue and Smith sedimentation tube (Fig. 117) consists of a large tube A, 4.5(diam.)×50-cm., surmounted by a smaller tube C, 2.5(diam.)×40-cm., with a jacketed manometer tube, B, 4-mm. i.d. joined through a 3-mm. stopcock D, 13 cm. from the bottom of A, and through a similar stopcock E, 8 cm. from the top of C. A scale S is placed inside the jacket, which is then evacuated to reduce temperature effects. A 2-mm. stopcock F is provided for adjustment of level. Increase in manometric sensitivity is attained by using two fluids in the manometer tube, the lower fluid being the sedimentation fluid free of any suspended matter, and the upper an immiscible fluid of lower density. Goodhue and Smith use 50% alcohol for the sedimentation fluid and decahydronaphthalene for the upper fluid. Density of the decahydronaphthalene is adjusted by additions of 1,2,4-trichlorobenzene, rendered visible by the addition of a small amount of a highly colored oil-soluble dye. After compounding, the top fluid is extracted with the sedimentation fluid to remove materials soluble in the latter and to saturate the top fluid with sedimentation fluid. Rise H in the manometer is given by the equation

$$H = \frac{h(G_s - G_l)}{(G_l - G_t)} \tag{52}$$

where h = settling height and G_t = density of the upper manometer liquid. It is apparent that H can be increased by decreasing the difference in density between the upper manometer liquid and the sedimentation liquid. A change in density of 0.00002 gm. per cc. is easily detected with the liquids mentioned, where G_l = 0.9280 gm./cc. and G_t = 0.900 gm. per cc.

Operation. Clean thoroughly and rinse apparatus with 50% alcohol. Fill to stopcock F with sedimentation fluid and a small amount of dispersing agent, if necessary. Fill manometer tube by tilting, and close stopcocks. Pour out some of the sedimentation fluid from A and introduce previously dispersed sample, about 7 gm., washing it down with more sedimentation fluid, and finally adjust level until overflow takes place through stopcock F. Place apparatus in constant-temperature bath. When temperature equilibrium is attained, stir suspension with the aid of a plunger and introduce upper manometric liquid into C, taking care not to disturb the upper layer of the suspension. Open stopcocks D and E. The top fluid rapidly replaces suspension fluid in part of the manometer tube and equilibrium is reached in about 2 min., after which readings may begin. The timer is started 30 sec. after the plunging of the suspension (time required for eddy currents to die out). For determination of size apply Eq. 48. For method of application see p. 124. Test sedimentation curves on sulphur, clay, and calcium arsenate are shown in Fig. 118.

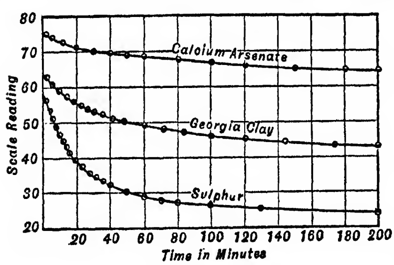

FIG. 118. Sedimentation curves (*Goodhue and Smith*).

Hydrometer method described by Pratolongo (*50 Le Stazioni sperimentali agrarie italiene 117*), Bouyoucos (*23 Soil Science 319, 343*), and adopted as a standard method of mechanical analysis of soils (*ASTM D 422-39*) consists in measuring the density of the suspension contained in a graduate at given intervals of time. In Pratolongo's method the plummet is suspended from a Westphal balance and its changes in weight with time are recorded, maintaining the plummet at the same depth within the suspension. Eq. 49 is directly applicable for the determination of the distribution curve; for method see p. 124. In the Bouyoucos and A.S.T.M. methods the depth to which the hydrometer is immersed depends upon the density of the suspension, hence it varies with time. If d_o = original reading of the hydrometer, d_∞ = hydrometer reading after long period of time, and d = reading at time t, then

$$V = \frac{2t^2}{a}\frac{d^2H}{dt^2} \tag{53}$$

where

$$H = \frac{d - d_o}{d_\infty - d_o}$$

In order to calculate the equivalent radius from Stokes' law, the distance through which the particles fall in a given time must be known. This distance is usually taken as the

distance between the surface of the suspension and the center of volume of the bulb of the hydrometer. This EFFECTIVE DISTANCE x_E may be computed from the constants of the hydrometer and the graduate used in making the test. Substitution of x_E in the equation $a = k\sqrt{x_E}$ gives the equivalent radius directly.

Procedure. A 3% suspension, properly dispersed by mechanical agitation, with addition of a suitable dispersing agent if necessary, is added to a graduate. The open end of the graduate is closed with a stopper, preferably cork, and the contents are mixed by inversion. Upon cessation of mixing, a timer is started and hydrometer readings are taken at desired intervals of time. After each reading the hydrometer is carefully removed, to prevent accumulation of solids thereon, wiped dry, and placed in another graduate containing water. The usual time intervals are 1, 3, 10 and 30 min., and 1, 3, 5, and 24 hr. Because of inability of the operator to follow rapid changes in density, this method should be used only with very fine suspension, say <400-m. for material with a gravity of 2.6. ACCURACY is increased by immersing the graduate in a constant-temperature bath and bringing the hydrometer to the same temperature before each measurement.

Simple sedimentation balance described by Bond (*A TP 1129*) consists of an ordinary analytical balance with the left-hand pan replaced by a sedimentation pan suspended in a 1,000-cc. cylindrical glass jar. The jar is fitted with a metal screw top which has a 4-mm. hole drilled in its exact center, to permit passage of the stem of the sedimentation pan. The pan is made from a noncorrosive metal disk 9-cm. diameter, slightly dished to prevent entrapment of air bubbles on the underside, and having a $^1/_2$-cm. rim around the edge. The stem, made of $^1/_8$-in. stainless-steel rod threaded at one end, is attached to the pan by means of bronze nuts and washers. The other end of the stem is shaped to hang from the balance-pan hanger. A notch 11 cm. above the pan is filed on the stem. The sedimentation jar rests on a V-shaped support which clears the balance-pan arrest; when so supported the sedimentation pan is $^1/_2$ cm. from the inside bottom of the jar. The stem carries a 00 rubber stopper which is used to seal the 4-mm. hole in the cover when shaking. A second hole in the cover is used for addition and removal of water and the introduction of a thermometer.

Operating procedure. Carefully determine the average inside diameter of the jar, the diameter of the sedimentation pan, depth of the liquid, and distance of pan from the inside bottom of the jar. Calculate the fractional volume of suspension that is vertically above the sedimentation pan; this fraction is called the volume fraction and is denoted by V_f. Calculate the weight of sample, W_s (in milligrams), required so that the ultimate weight increase of the pan will be 2,000 mg.

$$W_s = \frac{2{,}000G_s}{V_f(G_s - G_l)} \tag{54}$$

Fill the jar with a 0.25% solution of NaCl in distilled water up to the 11-cm. notch on the pan stem and prepare a tare weight which balances the immersed pan. The calculated weight of <200-m. sample (Eq. 54) is now added, together with 5 drops of a 15% solution of sodium silicate; the lid is sealed on with adhesive and the suspension is blunged with the sedimentation pan for 1 min. The stopper is now pressed down on the central hole in the lid and the jar swung through a 90° arc at the rate of one swing per second for one minute. At the end of the agitation period start a timer. Place the jar in the balance and determine and record the times required for the collected sediment to balance a series of weights added to the right-hand balance pan. The ultimate weight is obtained after overnight settling.

Bond found when using water as the dispersion medium that less material settled on the sedimentation pan and more on the bottom of the jar than could be accounted for by calculation; also that material that settled to the bottom of the jar outside the edges of the pan was finer than material on the pan, and that this discrepancy became more marked as the fineness of the sample increased. Reproducibility was improved by using a 0.25% sodium chloride solution. Errors arising from eddy currents are reduced by swinging the sedimentation jar through a 90° arc. Currents produced by temperature differences and by air bubbles precipitated during the run are reduced by bringing jar and contents to room temperature.

a See Art. 14.

FIG. 119. Comparison of size-distribution measurements on finely ground gold ore with the sedimentation balance and the Haultain Infrasizer.

ACCURACY of the method is difficult to estimate. It is claimed that sedimentation-balance results are in fair agreement with turbidimetric results. A comparison of a size-distribution curve determined by the sedimentation balance with one determined by the Infrasizer is shown in Fig. 119.

Calculation. Bond's method of computing the distribution curve differs from the method previously presented. Denoting weight in mg. of sediment on the pan by W and the settling time by t, a plot of t vs. t/W is made, and a straight line is drawn through the points. The intercept of this line on the

s/W-axis is denoted by y. The commonly observed upward curvature in the finer sizes is ascribed to mutual repulsion of the particles, and is avoided by using data in the 150- to 600-sec. range for determination of the straight line. The time required for a sphere of density G_s and size number 36 (see Sec. 4, Art. 17) to settle 11 cm. in a liquid of density G_l and viscosity b is calculated from Stokes' law thrown into the form

$$t_{36} = \frac{115{,}500b}{G_s - G_l} \tag{55}$$

It follows that $t_{37} = \frac{1}{2}t_{36}$, $t_{38} = \frac{1}{4}t_{36}$, $t_{35} = 2t_{36}$, etc. The percentage of weight, W_n, retained on size number n, and passing $n + 1$ can be computed from the equation

$$W_n = \frac{300t_n'^2 y}{(t_n' + y)(t_n' + 2y)(t_n' + 4y)} \tag{56}$$

where $t_n' = \dfrac{t_n}{1{,}000}$.

Example. Material was a sample of tube mill product from Lake Shore Gold Mines. $G_s = 2.78$, $V_f = 0.6830$, temperature = 22.6° C., $b = 0.00947$ poise. $W_s = (2{,}000 \times 2.78)/(0.683 \times 1.78) = 4{,}572$ mg. $t_{36} = (115{,}500 \times 0.00947)/1.78 = 614.4$ sec. $t_{36}' = t_{36}/1{,}000 = 0.614$. $y = 0.0900$ (determined by plotting sedimentation results).

Table 38. Computation by Eq. 56

n	t_n	$300t_n'^2y$	$t_n' + y$	$t_n' + 2y$	$t_n' + 4y$	$(t_n' + y) \times (t_n' + 2y) \times (t_n' + 4y)$	W_n, %

a Obtain by difference.

b $W_{38} = \dfrac{0.6356}{0.2435 \times 0.3335 \times 0.5135} = \dfrac{0.6356}{0.0417} = 15.23\%$.

Improved sedimentation balance, wherein a closer control of temperature, and automatic devices for the addition of weights and recording of time are introduced, are described by Oden (*17 Trans. Far. Soc. 327*) and Johnson (*16 Soil Science 365*).

Centrifuge method of determining side distribution is nothing more than a sedimentation method wherein the gravitational force is replaced by a centrifugal force. Such replacement enables the operator to vary at will the magnitude of the force producing settling and thus control the time required for testing. Centrifuging as presently practiced may be divided into two types according to whether the material under test is of suspensoid or colloidal size. This division is somewhat arbitrary but represents practice. Suspensoids have an upper limit of approximately 30-μ and a lower limit of 0.1-μ; colloids range from 0.1-μ down to giant-molecular dimensions. Centrifuging colloids is beyond the scope of this book; for its theory and practice see Svedberg (*Colloid Chemistry*, Reinhold Publ. Co., 1928). When a suspensoid is settled by centrifuging, the material settled in time t may be divided into two parts: (1) material with an equivalent diameter (Art. 18) equal to or greater than D, and (2) material which was settled even though its equivalent diameter was less than D (this is material that was originally near the bottom of the sedimentation tube). The equivalent diameter D may be calculated from Stokes' equation by replacing g by $(2\pi N/60)^2 l$ where N = r.p.m., and l = distance of particle from center of rotation, *i.e.*,

$$v_c = \frac{G_s - G_l}{18b} D^2 l \left(\frac{2\pi N}{60}\right)^2 \tag{57}$$

where v_c = centrifugal sedimentation velocity. Romwalter and Vendl (*72 KZ 1*) applied Oden's method (p. 121) and derived the following equation

$$\int_0^D U\,dD = \frac{1}{4.6 \log r/r'} \frac{r^2 - r'^2}{r'^2} t \frac{dw}{dt} \tag{58}$$

where $U = \dfrac{df}{dD}$ (see p. 121), r = distance from axis of rotation to bottom of centrifuge

tube, r' = distance from axis of rotation to the meniscus of the suspension, and w = weight of material sedimented in time t. Solving Eq. 57 for D gives

$$D = \frac{6}{\left(\frac{2\pi N}{60}\right)}\left(\frac{b \ln r/r'}{2(G_s - G_l)t}\right)^{1/2} \tag{59}$$

Procedure. Martin (*11 IECA 471*) used a centrifuge free of vibration and housed in a constant-temperature room, run at 1,300 r.p.m., and having tubes which were 15(diam.)×35-mm. flat-bottom vials. A tube was filled with suspension, weighed, then centrifuged for t min., after which it was removed to a special holder and all of the liquid above 2 mm. from the bottom was drawn off by means of a capillary pipette. The withdrawn liquid was analyzed for suspended solids, chemically or otherwise. The vial sediment was dried, weighed, and the percentage settled in time t calculated.

Accuracy of the method, as checked by microscopic determinations of size, appears to be fairly good. Table 39 compares results with centrifuge and microscope. The average particle sizes, 1.6-μ for the former and 1.92-μ for the latter, compare fairly in light of the approximations in calculation. Martin cites REPRODUCIBILITY of the order of magnitude of ±5% (see Fig. 120). Attainment of such accuracy and reproducibility presupposes proper dispersion of the powder in the sedimentation liquid. TIME required for testing depends upon the number of points determined on the sedimentation curve; 2 to 3 days appears to be average for a relatively complete test.

Table 39. Centrifugal *vs.* microscopic determination of average size (*after Martin*) *a*

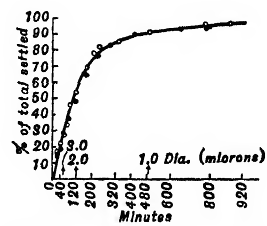

FIG. 120. Reproducibility in centrifuge sizing.

17. SURFACE MEASUREMENT

In the case of many industrial minerals, requirements as to fineness are measured more satisfactorily by estimates of particle surface per unit of weight (SPECIFIC SURFACE) than by measures of particle size. This is particularly true when after-use of the material involves chemical reaction. Hence in such industries surface measurement substitutes more or less completely for particle-size measurement as a tool of control. Even where particle size is of interest, cases arise in which estimation thereof from surface measurement is more rapid, or more readily effected than direct size estimation.

Turbidimetry

Turbidity of a suspension is directly related to the specific surface and may be used as an indirect measure of particle-size distribution. TURBIDITY is defined as the logarithmic ratio of the intensity I_0 of the light transmitted by a given thickness of clear suspending medium to the intensity I of the light transmitted by the same (constant) source, through an equal thickness of suspension, *i.e.*, turbidity = $\log (I_0/I) = \log I_0 - \log I$. Turbidity is proportional to the concentration and to the specific surface of the powder. This relationship fails unless particles are completely opaque and are larger than about 3-μ; finer particles produce diffraction effects which follow a different law. The rapidity of the method, average 30 to 45 min. for determination and calculation, recommends it. It is standard procedure in control of clinker grinding in cement manufacture.

Wagner turbidimeter (*33 ASTM 553*) is shown in Fig. 121. Light source a is a 6-cp. lamp on a 6-v. storage battery with rheostat control; it is mounted in a parabolic reflector to produce a substantially parallel beam passing through a water cooling cell b, a rectangular slit in an opaque shield c, a sedimentation tank d, another shield with rectangular slit, and thence through a filter to a photoelectric cell e (Weston Photronic), all enclosed in a substantially lightproof cabinet f, about 6×12×18-in. Current generated by the cell is measured by a low-resistance microammeter. The light source, cooling cell, slit and photo-cell are mounted on a movable shelf g which is raised and lowered as

indicated by handle h. An opening is cut out of the bottom of f to isolate the sedimentation tank, which is mounted on an independent base i, to reduce vibration of the tank when shelf g is moved. A pointer j attached to the shelf indicates the position of the light assembly against a scale k on the outside of the cabinet.

Calibration. Adjust light intensity I_0 to 100 microamperes as follows: A suspension containing 0.5 gm. of a powder is placed in the tank and the microammeter read at some time after agitation ceases (usually 1 min. for the 30- to 60-μ level). A second suspension containing 1.0 gm. of the same powder is placed in the tank and a reading taken at the same level after the same interval of time has elapsed. These two readings are plotted directly as ordinates on semilogarithmic paper (logarithmic scale on intensity) against the weight of the sample, and a straight line is drawn through them. The intercept of the line with the zero weight ordinate is I_0. If the value obtained is other than 100 microamperes, the rheostat setting of the lamp is changed and I_0 redetermined. When the lamp is properly adjusted the filter is placed in the light path, the tank is removed, and a reading is taken. This permanent reference value is $I_0 \times f$, where f = filter factor.

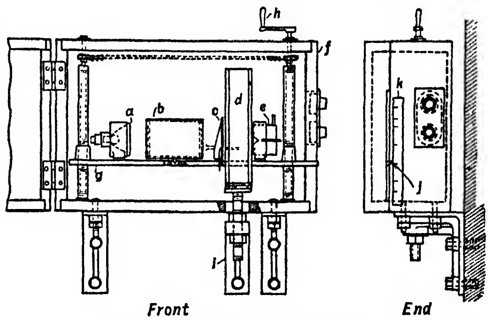

FIG. 121. Wagner turbidimeter.

Time intervals at which readings are taken may be obtained either by calculation (Eq. 60) or by use of a timing burette, which consists of a glass tube (38 ± 4 cm. long and 1.9 ± 0.2 cm. diameter) having a capillary tube (17.5 ± 2.5 cm. long, 0.09 ± 0.005 cm. diameter) fused into the lower end, the upper end being flared to serve as a funnel.

Calibration of timing burette. (1) Calculate times of flow from the burette corresponding to the settling times for the different sized particles using Stokes' law in the form

$$t = \frac{1{,}837{,}000hb}{(d_s - d_l)D^2} \tag{60}$$

where t = settling time, sec.; h = depth from top of suspension to level of light, cm.; b = viscosity of suspending liquid, poises; d_s = density of solid, gm. per cc.; d_l = density of liquid; D = particle diameter, μ. (The diameter of an irregularly shaped particle is taken as the diameter, calculated from Stokes' law, of a sphere of the same density and falling velocity as the particle.) (2) Fill burette with suspension fluid; viscosity and density at calibration temperature are known. (3) Start timing clock at instant fluid drains past zero line. (4) Note levels reached by draining fluid at times calculated from Eq. 60 and mark burette scale with the corresponding diameters. Since rate of flow through burette varies with changes in viscosity and density of fluid in the same manner as the settling time, the timing burette automatically corrects the settling times (or times of flow) for small changes in temperature, viscosity and fluid density.

In use, the burette is filled with suspension fluid and sedimentation is allowed to start when fluid in burette drains past zero line. Turbidimeter readings are taken when draining fluid passes the calibration marks corresponding to diameters 60, 55, etc.

Operation. A 0.3- to 0.5-gm. sample is dispersed in the suspending liquid, using a dispersing agent, if necessary, and is placed in the sedimentation tank with enough additional liquid to bring volume to the mark. Tank windows are wiped clean. With the filter in place adjust light intensity to a proper value ($I_0 \times f$) (for calibration see above) by taking readings at 1-min. intervals until lamp and photocell are in equilibrium, as is indicated by constancy of readings. Place pointer j at the 30~60-μ mark. Oscillate the sedimentation tank, place it in position, and record time. Remove the filter and take readings at times t_{60}, t_{55}, t_{50} . . . t_{30} corresponding to diameters 60-, 55-, 50-, 45-, 40-, 35-, and 30-μ as calculated for the material and instrument. Then raise the shelf to the 25-μ mark and read at times t_{25}, etc., until all sizes are covered.

At end of test, the value of $I_0 \times f$ should be redetermined, and should agree within 0.2 microamperes with the value obtained at the beginning.

Basis of method lies in hydrodynamics and optics. When a beam of light is incident upon a suspension of opaque particles its intensity is reduced, because of nontransmittancy of the opaque bodies. But, since the particles are not BLACK BODIES (*i.e.*, perfect absorbers of light) reflection occurs in an amount and direction depending upon their reflectivity, the illuminated surface area, and their surface configuration. This reflected light falls on the shadowed side of other suspended particles and thereby undergoes further reflection. As a result, a suspension transmits light in all possible directions, but with differing intensities. Intensity in any direction depends upon the surface area and number of particles. In the Wagner turbidimeter intensity in the direction of the original beam is measured; in the various forms of the Tyndallometer (see p. 129) the intensity of the light scattered at right angles to the original beam is measured. There is further loss in intensity owing to absorption by the suspending medium.

If the dilution of the suspension is such as to permit free settling, and if the size of the particles (<80-μ) is such that settling takes place according to Stokes' law, then after a time interval t all particles larger

Table 40. Turbidimetric calculations on a cement sample

than a diameter D will have fallen below the level h of the slit delineating the light beam, and the change in intensity of the transmitted light will be due to the removal of these larger particles. Particles smaller than D that fall out of the light path are replaced by particles of like size from the upper layers, hence do not affect the intensity. Hence microammeter readings taken at times t_1, t_2, t_3, . . . afford a measure of surface area of the particles in the original suspension smaller than the corresponding diameters D_1, D_2, D_3, . . ., as calculated from Stokes' law.

Surface area of all particles smaller than D is directly proportional to the turbidity, and is given by the empirical equation

$$A_S = c(\log I_0 - \log I_D) \tag{61}$$

where A_S = surface area, in sq. cm., of all particles smaller than D diameter, I_0 = intensity of light, in microamperes, transmitted by clear liquid; I_D = intensity of light transmitted by suspension after the time interval required for a particle D diameter to settle from the surface of the suspension to the center line of the light beam has elapsed; c = the transmittancy constant. The use of microamperes as a measure of intensity is justified by the direct proportionality existing between intensity of light and the current generated by the photo-cell; for photo-cells not exhibiting linear characteristics in the useful range this use is not justified. The transmittancy constant c depends upon reflectivity, transparency, shape, and size of particles and is assumed independent of size; the assumption is untenable when particle size is less than 2- or 3-μ.

Transmittancy is evaluated by equation

$$c = \frac{1.2 \times 10^4 \times \dfrac{W_{60}}{G_s}}{1.5 + 0.75 \log I_{7.5} + \log I_{10} + \log I_{15} + \cdots \log I_{55} - 11.5 \log I_{60}} \tag{62}$$

where W_{60} = weight in grams of <325-m. material in sample. Neglect surface area of >60-μ particles.

Specific surface S_0 of the powder is given by

$$S_0 = \frac{1.2 \times 10^2 \times \dfrac{q}{G_s} \times (2 - \log I_{60})}{1.5 + 0.75 \log I_{7.5} + \log I_{10} + \cdots \log I_{55} - 11.5 \log I_{60}} \tag{63}$$

where q = % <325-m. Particles larger than 60-μ are relatively few in turbidimeter feeds and have relatively small surface area per unit weight, hence produce insignificant changes in microammeter readings and may be neglected.

Weight of a fraction is given by

$$W_{D_1 \sim D} = \frac{G_s}{6} \times 10^{-4} \times \left(\frac{D + D_1}{2}\right) \times c \times (\log I_D - \log I_{D_1}) \tag{64}$$

Table 41. Comparison between turbidimetric, microscopic, and air-elutriation determinations

Micron range	Percentages: Average of 2 microscope counts		Average of 8 turbidimetric tests		Roller air elutriation
0~5	1.0		0.6		1.6
5~10	5.9		4.3		4.0
10~20	15.9		19.0		16.6
20~30	16.4	35.5	17.8	35.3	34.4
30~40	19.1		17.5		
40~50	20.2	41.7	20.3	40.7	43.4
>50	21.5		20.4		

Calculations are facilitated by the use of equal particle-diameter intervals. Maximum particle diameter used is a matter of experience; it should be such that the microammeter

reading for the next coarser size differs by less than 0.1 microampere from the reading for D_{max}. For turbidimetric work on copper powders, the METALS DISINTEGRATING Co. uses a $D_{max} = 50\text{-}\mu$, and determines diameter and falling velocity of difficult grains separately.

Example of turbidimetric calculation on 1-gm. sample of cement, 89.7% <325-m. sp. gr., 3.15. *f*, 20.5 before and after. Turbidimetric sample 0.3 gm. Readings, see Table 40. TRANSMITTANCY *c* from Eq. 62, 1,985; specific surface from Eq. 63, 1,900 sq. cm. per gm.

Table 42. Relation between screen and turbidimetric measurements for cement

Mesh size, % passing		Surface area sq. cm. per gm.
200	325	
70 to 75	60 to 70	1,000
80 to 85	65 to 75	1,200
90 to 95	87 to 90	1,400
93 to 97	90 to 93	1,600
97 to 99	93 to 96	1,800
99 to 99.7	96 to 98	2,000
All.......	98 to 99	2,300
All......	99.5 to 99.8	2,600

Reproducibility of the method, as measured by the per cent. average deviation, is of the order of 6 to 7%. Comparison of turbidimetric results with those obtained by microscopic count and by air elutriation is given in Table 41.

Screen equivalents of turbidimetric measurements of cement are given in Table 42.

Tyndallometry

Tyndallometer has been suggested by a number of investigators as a tool for surface and size measurement. The method is based upon the fact that light incident upon a particle small compared to the wave length is reflection-scattered in all directions, and is polarized to an extent which depends upon the angle the scattered light makes with the incident beam, being completely plane polarized in the 90° position. As particle size increases polarization decreases and finally vanishes when the particles are large compared to the wave length. Attempts to utilize this phenomenon for size measurement have not proved particularly successful (Stutz, *210 JFI 67*), but Gamble and Barnett (*9 IECA 310*) have adapted and improved an apparatus suggested by Pfund (*24 J. Opt. Soc. Amer. 143*) for determining scattering in the near infrared, and report differentiation between samples of zinc oxide that appear microscopically to have the same size.

Surface-reaction Methods

Under this heading are grouped methods depending upon established surface reactions of chemical-solution and metathetic types, so-called adsorption methods, and methods involving measurement of the heat of wetting. All, beyond possibility for argument, involve extension of the reaction field along cracks into the interior of the solid, and none can, therefore, pretend to a measurement of superficial surface upon which to found an estimate of particle size or other function of superficial surface. They may, on the other hand, give a useful basis for estimates of surface-chemical activity.

Dissolution

Dissolution methods of surface measurement are based on Wenzel's law that rate of reaction between solids and liquids is proportional to the area of contact. The rate of reaction decreases with time, since reaction is accompanied by a decrease in concentration of solvent, a decrease in surface area, and an increase in concentration of reaction products. Consequently the dissolution rate must be determined for zero time, when no change in liquid or solid has taken place. This is possible only by extrapolation of the rate curve to zero time. The method with any given solvent is applicable to a single solid only, since it is usually impossible to find a solvent having equal dissolution rates for different solids or, therefore, for the components of a mixture of solids.

Success in use is dependent upon proper choice of solvent. Conditions limiting such choice are: (*a*) The diffusion rate must exceed the dissolution rate, or the rate measured will be the diffusion rate. (*b*) The reaction product should not be gaseous, because mechanical difficulties are then introduced. (*c*) The rate curve should be reasonably flat to assure accuracy in extrapolation. Curves of excessive curvature result when the reaction is autocatalytic, when the equilibrium point is reached or approached in the time required for dissolution, when the reaction products protect the surface from further attack by the solvent, when the solvent concentration is improper, *i.e.*, when the change in dissolution rate diminishes too rapidly, as may occur when concentration of solvent is too low, or when the solvent dissolves too large or too small a quantity of solid.

Wolf (*35 Ztschr. angew. Chem. 138*) has used a mixture of sodium carbonate and sodium hydroxide as the solvent for powdered glass; Kraige (*24 RP 65*) used hydrochloric acid for calcite and limestone; Martin (*25 CerS 51*) and Gross (*Bul 402 USBM*) have used hydrofluoric acid for quartz.

Procedure perfected by Gross is as follows: Hydrofluoric acid (3.66 *N*) is placed in a Bakelite tube stoppered at both ends and is brought to a temperature of about 23° C. An accurately weighed sample of quartz is introduced into the tube and tube and contents are placed in a constant-temperature bath, the tube being revolved to stir. Just before the allotted time of the test has elapsed, the tube is removed and its contents are rapidly filtered and washed. Dissolution time is that elapsed between introduction of solid into the tube and application of wash water. Tests are made for 1/2-, 1-, 1 1/2-, and 2-hr. periods on different samples cut out from a lot. The filtered quartz is ignited and weighed and the quantity dissolved computed by difference. Results of a test are shown in Fig. 122. Rate and cumulative curves may be combined empirically to produce a straight line, thus

$$KQ + R = R_0 + kt \tag{65}$$

where K and k = constants, Q = cumulative % dissolved, R = % dissolved per hr., R_0 = initial rate, and t = time, in hr. of test. The relation holds for dissolution times up to 9 hr. for quartz ranging

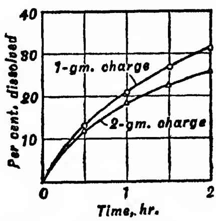

FIG. 122. Results of dissolution tests on quartz.

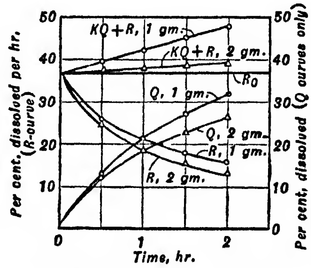

FIG. 123. Extrapolation for initial rate.

from 3-m. to 1-μ. Values of the unknowns K, R_0, and k may be determined from three sets of values for Q, R, and t; the fourth set may be used as a check. Checking is done by means of the following equations derived from Eq. 65:

$$R = \frac{R_0 + kt}{1 + Kt}; \quad Q = \frac{R_0t + kt^2}{1 + Kt}$$

Fig. 123 shows the $(KQ + R)$ lines extrapolated to zero time, giving initial rate.

Initial rate in hydrofluoric acid leaching of quartz was attempted to be related to surface area by comparing the weight of a silver coating of crushed quartz with that on quartz crystals of known area. Accuracy of the silver-coating method of comparing surface areas is not high, hence the absolute surface areas determined by the dissolution method are not particularly accurate; comparisons of initial rates are probably more accurate. REPRODUCIBILITY is excellent, duplicate runs agreeing within 0.1%.

Adsorption

Adsorption methods of surface measurement may be divided into two classes according as the adsorption takes place in a gas or in solution. In both cases experimental procedure is directed toward determination of the quantity of material adsorbed. On the assumption that the adsorbed material forms a closely packed monomolecular layer over the surface of the powder, and from a knowledge of the molecular dimensions and orientation of the molecule, the so-called absolute specific surface may be calculated. The validity of the method as an absolute one is questionable; as a relative method it stands on firmer ground.

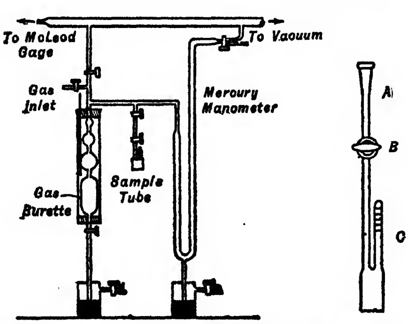

FIG. 124. Mackower gas-adsorption apparatus.

Gas adsorption methods have been described by Emmett *et al.* (*59 ACS 310, 45 Soil Science 57*) and Mackower (*2 Proc. Soil Sci. Soc. Amer. 101*).

Mackower's apparatus, which is a modification of the Emmett apparatus, is shown in Fig. 124.

Procedure. A sample, sufficient to give a surface area in excess of 10,000 sq. cm., is placed in the sample tube, which is then evacuated to remove moisture and other adsorbed vaporizable materials; evacuation is continued until pressure is less than 10^{-5} mm. of mercury. This may take as long as 4 days. The sample bottle is then placed in a liquid-nitrogen bath and the free space within the sample bottle is determined by displacement with helium, from which the density of the material may be calculated, knowing the weight of helium introduced and the volume and temperature prevailing. Helium

is removed by pumping and nitrogen is admitted while the sample bottle is still in the liquid-nitrogen bath. After equilibrium is attained, as indicated by constant pressure for a constant temperature, the temperature and volume of gas remaining in the free space are determined, from which the amount of adsorbed nitrogen may be calculated. Readings at higher pressures may be taken by forcing mercury into the gas burette. A plot of pressure against volume of nitrogen adsorbed is shown in Fig. 125; the resulting curves are typical van der Waals isotherms. If the linear portion (at low pressures) of the curve is extrapolated, the volume-axis intercept gives the volume of gas required to form a monomolecular layer of gas on the surface, with an error of about 15%. To correct for this error Emmett suggested using a corrected intercept point and devised the following method of plotting for obtaining it. The apparatus and procedure for this method are complicated and should not be attempted without reference to the original literature cited.

Calculations. Relation between the various quantities is given by

$$\frac{p}{V(P_0 - P)} = \frac{1}{V_m K} + \frac{K-1}{V_m K} \cdot \frac{p}{p_0} \tag{66}$$

where V = volume of gas adsorbed at pressure P and at a temperature at which the vapor pressure of the liquefied gas is P_0, V_m = volume of gas, in cc., required to form a monolayer, and K = constant related exponentially to the difference between the heat of liquefaction of the adsorbate and its heat of adsorption. If the data for the low-pressure end of the isotherm are plotted with $P/V(P_0 - P)$ as ordinates and P/P_0 as abscissae, a straight line results, the intercept of which is $1/V_mK$ and the slope $(K-1)/V_mK$. Solution of these simultaneous equations gives values for V_m and K. From this volume at normal temperature and pressure the number of molecules can be calculated, using Avogadro's number. The cross-sectional area of a molecule can be calculated from its diameter (13.8 Å for N was obtained by Gaudin and Bowdish (*A TP 1666*) by comparison with glass spheres of known surface), hence the product of this area and the number of molecules contained in the adsorbed volume of gas gives the projected area covered by the gas. This area multiplied by a factor which makes allowance for the void space in the type of planar packing that is assumed gives the area of the powder.

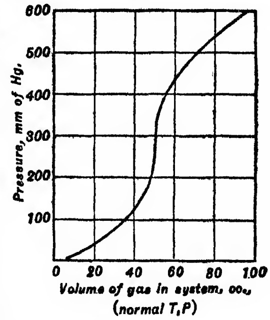

FIG. 125. Typical adsorption curve for Mackower apparatus.

Determinations for a number of fine powders by this method compared with determinations by other methods are given in Table 43. Other gases have been used, *viz.*, O, A, CO, CO_2, and SO_2, and other solids, *e.g.*, iron synthetic-ammonia catalysts, metallic-copper catalysts, pumice, nickel-oxide catalyst on pumice, nickel on pumice, hydrated and anhydrous copper sulphate, potassium chloride, crystalline chromium oxide, chromium-oxide gel, Glaucosil, silica gel, and soils. Charcoal does not yield an S-curve.

Liquid adsorption methods abound in the literature. A typical method is described by Harkins and Gans (*53 ACS 2804*). A sample of titanic oxide powder was dried in a high vacuum at high temperature. Thereafter the cool, dry powder was immersed in a solution of oleic acid in dry benzene (see Fig. 126 for concentrations) and the suspension shaken until equilibrium was reached, which was determined by permitting the powder to settle, withdrawing a sample of supernatant liquid, analyzing for oleic acid, and repeating until the analyses for successive withdrawals duplicated. Fig. 126 shows results. Harkins interpreted the linear portion of the curve to indicate the formation of a condensed oleic-acid film upon the surface of the powder. On the basis of the facts presented, and in view of the overwhelming evidence to the contrary, this conclusion is untenable; actually a surface reaction has occurred (see Sec. 12, Art. 3). Using a figure of 20.0 sq. Å as the cross-sectional area of the molecule (obtained from air-liquid interface work) areas of 22.9 sq. m. per cc. (3.89 gm.) for sample I, and 14.4 sq. m. per cc. for a different sample, II, were calculated. The ratio of these values is 1.59. When propyl alcohol was adsorbed, the ratio of the calculated areas for these samples was 1.53. The ratio of areas from heat of wetting (see p. 133) was 1.53. The area of sample II calculated from microscopic determination was 13.8 sq. m. per cc.

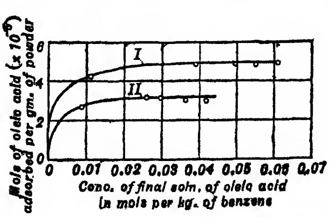

FIG. 126. Adsorption of oleate ion from benzene onto titanic oxide (*after Harkins and Gans*).

Other liquid-adsorption methods are described by Askey and Feachem (*57 SCI 272*), *Paneth*, and *Hahn*.

Radioactive tracer method **(see p. 94) is based on: (*a*) kinetic exchange between ions of the crystal lattice and a radioactive ion in solution, capable of isomorphous crystal formation with the oppositely charged ion of the lattice; (*b*) surface coverage by radioactive ions from solution; or (*c*) surface**

coverage by radioactive molecules from solution. Exchange of lead ions between a saturated solution of radioactive lead sulphate (from thorium B) and a powder of ordinary lead sulphate, was used by *Paneth* to determine the surface area of the latter. Surface was also calculated from microscopic determinations of average height and width of the lead sulphate crystals; the difference between the results of the two methods ranged from 2 to 58% for eight different powders. With lead chromate powders of more perfect crystalline form, on which microscopic determination of surface is more readily and accurately made, the discrepancy between the results of the microscopic and radioactive methods was less than 10%; with strontium sulphate (isomorphous with lead sulphate) powders of almost perfect crystals the difference vanished. The kinetic exchange method is usually applicable to artificial minerals, and such natural minerals as exhibit a mosaic structure, *e.g.*, natural minerals such as crocoite, wulfenite, cerussite, etc., which are composed of smaller crystals oriented at random; natural minerals which exhibit a high degree of regularity (*e.g.*, galena, anglesite, barite, selenite, etc.) do not give a measurable exchange.

Heat of wetting as a method of surface measurement has been suggested by a number of investigators. The method attempts to measure the energy changes associated with the purely physical process involved in the formation of a solid-liquid interface; the heat of wetting being a function primarily of the interfacial area and tension. Unfortunately, energy changes associated with chemical surface reactions and dependent upon the previous history of the material interfere with the determination. In addition, and apart from any chemical activity, the interfacial tension is affected in some unknown way by the age of the solid surface, consequently surface determinations by this method cannot be considered reliable.

Permeability

Permeability methods give a direct measure of specific surface and an indirect determination of average size. If a fluid, usually air or water, is percolated through a porous medium of uniform cross-sectional area A sq. cm. and thickness l (cm.), the rate of flow is given by Darcy's law

$$v = Q/A = KP/bl \tag{67}$$

where v = rate of flow in cm. per sec., Q = volume of fluid flow through the bed in cc. per sec., P = the pressure difference driving the percolation fluid, in gm. per sq. cm., b = viscosity of fluid in poises, and K = a proportionality constant called the PERMEABILITY of the porous medium. K is a specific property of the porous bed, which is independent of the bed dimensions, of the driving pressure, and of the viscosity of the fluid. The permeability is calculable on theoretical grounds (Kozeny, *22 Wasserkr. u. Wasserwirts. 67, 86*) for a bed of rigid grains according to the expression

$$K = \frac{gB^3}{5S_0^2(1 - B)^2} \tag{68}$$

where g = acceleration due to gravity in cm. per sec. per sec., S_0 = specific surface in sq. cm. per gm., B = porosity or fractional void space in the bed.

Validity of Eq. 68 has been demonstrated experimentally by Carman (*15 ICE 150; 57 SCI 225 T*). Solving Eq. 68 for specific surface

$$S_0 = \sqrt{\frac{gB^3}{5K(1 - B)^2}} = 14\sqrt{\frac{1}{K} \cdot \frac{B^3}{(1 - B)^2}} \tag{69}$$

Carman tested this equation, using particles of known geometric shape, for a wide variety of materials with porosities ranging from 0.26 to 0.90. The geometrical specific surface was in good agreement with the specific surface calculated from Eq. 68, independently of variations in porosity. When mixtures in known proportions of particles of known and varying specific surface were tested, the predicted specific surface was in agreement with that calculated from the permeability.

Carman fluid percolator (*39 JCM 266*) consists of a permeability tube a (Fig. 127) of accurately known uniform cross-sectional area A sq. cm., 1.8- to 2-mm. diameter and 5 to 10 times this length, connected by means of a ground glass joint b and bent tube c, containing a stopcock i, to the collecting bottle d and thence by tube e with a vacuum receiver equipped with a pressure regulator and manometer. At f is located a piece of Monel metal filter cloth supported by a copper spiral spring g. The filter cloth carries the sample bed k. With fine-grained samples, the filter cloth is precoated with a thin layer, ±0.5-mm., of kieselguhr, colored black with carbon or red with ferric oxide so as to make clear the boundary between granular bed and kieselguhr. The resistance, as measured by pressure drop, of the filter cloth plus kieselguhr should not exceed 1 to 2% of the resistance of the bed. The reservoir m for percolating liquid is a volumetric cylinder fitted with a discharge

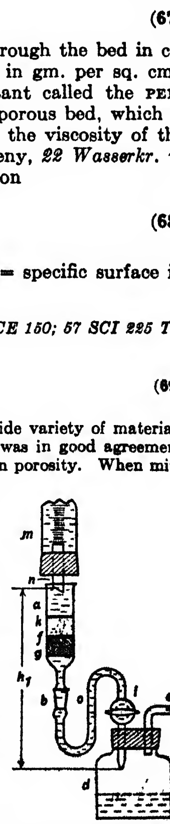

FIG. 127. Carman fluid percolator.

tube n, with beveled bottom, of such diameter that with a slow flow of percolating liquid, air flows upward and liquid downward through n at such a rate as to maintain level h_1 in a as indicated.

Procedure. A sample of known weight is placed in a beaker, is thoroughly wetted by additions of small quantities of percolation liquid preheated to its boiling point, and, stirring with a rod equipped with a rubber policeman, additions are continued until a volume of liquid some 5 to 10 times the volume of the powder has been added. Dispersion of the powder in the liquid must be as complete as possible; it may be aided by addition of suitable dispersing agents (Sec. 12, Art. 8). The dispersed pulp is cooled to room temperature, stirred and washed gently into the percolation tube. If a precoat of kieselguhr is used, this addition must not disturb it; protection may be had by first covering the precoat with a 1-cm. layer of percolation fluid. After addition of the sample, suction is applied and the sample is stirred so as to prevent stratification. Suction is continued until all the powder is drawn into the bed. The bed thickness should be such that vacuum need not exceed 15 or 20 cm. of mercury with organic liquids, or 40 to 50 cm. of mercury with water. The thickness l of the bed is determined by measurement at several points of the circumference. Flow should next be started and suction adjusted to a constant flow rate through n.

Example of measurement and calculation of specific surface of a cement sample. Density of cement $G_s = 3.05$ gm. per cc.; sample weight $W = 4.27$ gm.; depth of bed $L =$ (arithmetic average at four points around periphery) 0.96 cm.; cross-sectional area of permeability tube $A = 2.87$ sq. cm.; viscosity b of liquid (alcohol-acetone mixture) at 18° C. = 0.0046 poise; density of liquid at 18° C., $G_l = 0.792$ gm. per cc.; manometer reading = 10.05 cm. of Hg; head h_1 (see Fig. 127) = 13.0 cm.; resistance of support = <1% (negligible); average volume rate of flow $Q = 0.0255$ cc. per sec.
From these data

$$P = 10.05 \times 13.55 + 13.0 \times 0.792 = 146.5 \text{ gm. per sq. cm.}$$

From Eq. 67 and $Q = Av$,

$$K = \frac{QbL}{PA} = \frac{0.0255 \times 0.0046 \times 0.96}{147 \times 2.87} = 2.66 \times 10^{-7} \text{ cc. per sec. per sec.}$$

$$B = \left(1 - \frac{W}{G_s AL}\right) = \left(1 - \frac{4.27}{3.05 \times 2.87 \times 0.96}\right) = 0.492$$

$$S_0 = 14 \sqrt{\frac{(0.492)^3}{2.66 \times 10^{-7}(1 - 0.492)^2}} = 18{,}400 \text{ sq. cm. per cc. (from Eq. 69)}$$

The equivalent particle size, D_A, is the diameter of a spherical particle such that a gram of such particles would have the same surface area as the specific surface of the powder tested, *i.e.*

$$D_A = \frac{6}{S_0} = \frac{6}{18{,}400} = 3.3\text{-}\mu \quad \text{(see Eq. 90)}$$

Carman reports as the principal limitation of the method difficulty in obtaining good dispersion of powder in fluid, and sets 1-μ as the probable lower size limit. He also shows that flocculation has less effect upon permeability results than upon results of sedimentation methods. ACCURACY was tested with glass spheres of three different sizes. Each fraction was analyzed microscopically, a count of 1,000 particles being made in each case. Comparison is shown in Table 44.

Table 44. Comparison of percolation and microscopic determinations of specific surface of glass spheres (*after Carman*)

Sample No.	Specific surface, sq. cm. per gm.		Average diameter, μ	
	Percolation	Microscope	Percolation	Microscope
1	2,090	2,070	28.7	29
2	987	950	61	63
3	653	653	92	92

Specific surface of binary mixtures of powders A and B with specific surfaces S_{0A} and S_{0B}, possess specific surfaces S_0 as given by

$$S_0 = xS_{0A} + (1 - x)S_{0B} \tag{70}$$

where x is the weight fraction of A. Tests with quartz powders verified this law of composition.

Air percolator described by Gooden and Smith (*12 IECA 479*), shown in Fig. 128, consists of a Bunsen valve a (slitted rubber tube) attached to air supply, a screw clamp b for fine adjustment of air flow, a pressure regulator controlled by height of water in standpipe c; a calcium chloride drying tube d, a sample tube e which carries the powder under test supported by a porous plug f made of No. 40 copper wire, a water-filled manometer g, a leveling tube h for adjustment of water level in the manometer, and a U-tube i, one arm of which is filled with compacted fine sand which acts as a resistor. The resistor and manometer constitute a flow meter.

Procedure. A known weight of powder is placed in sample tube e and compacted therein by tapping the tube until the apparent volume remains constant, thus insuring uniform porosity. Tube e is then

inserted in the air line by rubber tubing, and air supply is turned on and adjusted to give gentle bubbling. When the manometer readings become constant, a reading is taken and mean diameter D_m or specific surface S_0 is calculated from equation

$$D_m = \frac{6}{S_0} = \frac{60{,}000}{14}\sqrt{\frac{bCFG_s l^2 W^2}{(VG_s - W)^3(P - F)}} \tag{71}$$

where b = viscosity of air in poises, C = conductance (*i.e.*, the inverse of flowmeter resistance) in cc. per sec. per unit pressure (gm. per sq. cm.), G_s = density of material in gram per cc., l = length

or height of compacted sample in cm., m = weight of sample in grams, V = apparent volume of compacted bed in cc., P = over-all pressure in grams per sq. cm., and F = pressure difference across flowmeter resistance.

Accuracy was tested by a comparison of the microscopically determined surface-weighted average diameter with the surface-weighted average diameter calculated from the permeability results on separate fractions of powdered quartz (Table 45). Considering the approximations involved in the microscopic determination, agreement was good. Results obtained are reported to be REPRODUCIBLE within 5% in the range of 1- to 50-μ. TIME required for a test ranges from several minutes for free-flowing coarse or fine samples to an hour with some extremely fine samples. The authors describe an automatic calculator which greatly facilitates calculations and reduces testing time.

Coercimetry

The coercimetric method of surface measurement is based upon the existence of a linear relationship between the magnetization coercive force and the specific surface of a magnetic powder (*3268 RI 83*). If either total magnetic induction B or the magnetization density, $4\pi I$, is plotted against the magnetic field intensity, H, there results a characteristic hysteresis loop (Fig. 129). The H-axis intercepts of these curves determine the magnitude of the coercive forces H_{CB} and H_{CI}, which may be defined as the reverse magnetic field intensity required to reduce the total magnetic induction or the magnetization density of a previously magnetically saturated substance to zero; the proper unit of measure of the coercive force is the oersted, though the gauss is sometimes used. The B- or $4\pi I$-intercept of these curves determines the magnitude of the REMANENCE B_r which is defined as the magnetic force retained when the imposed magnetic field vanishes. Since B and $4\pi I$ are both measured in gausses the B- and $4\pi I$-intercepts are equal, as may be seen from the relationship $B = H + 4\pi I$. It should be noted that it is the magnetization-density intercept that is equal to the remanence and not the intensity-of-magnetization intercept, *i.e.*, I-intercept.

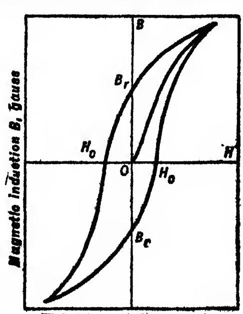

FIG. 129. Characteristic hysteresis loop of a ferromagnetic substance.

Coercimeter (Davis and Hartenheim, *7 RSI 147;* DeVaney and Coghill, *134 A 282*) consists of a long tube A (Fig. 130) of glass or Bakelite on which the primary solenoid B is wound. A secondary coil C is mounted on wheels and runs on a miniature track D, thereby enabling the operator to vary the location of C coaxially relative to B. The leads of the secondary coil with sufficient turns to produce the necessary impulse on the galvanometer available are connected to a high-sensitivity ballistic galvanometer E.

The primary coil B (464 turns No. 18 enameled wire) is connected to the power supply F (a 12-volt storage battery), and a resistor G in series is used to control current. The sample holder H is a brass tube, closed at one end and fitted with a screw top at the other end.

Procedure. Fill sample holder with material under test and compact by tapping. Screw top on tightly enough to hold grains in position, so that they will not move under the action of the magnetic field. Place capsule and contents between the poles of a strong electromagnet, *e.g.*, I, and saturate magnetically. This requires about 5 to 10 sec. After saturation, place the capsule in holder J and insert to the mid-point of the primary coil. Balance the magnetic field of primary against the field of the magnetized specimen by varying the current to the primary until there is no galvanometer deflection when the secondary is suddenly moved. Determine the current to the primary by means of ammeter K (0.1, 1.0, 10-amp.). This reading in amperes multiplied by an instrument constant gives the coercive force H_{CI} in oersteds. The end point may also be determined by taking several galvanometer deflections in each direction, provided they are not too large, and plotting these against the current to the primary; the current intercept of the resulting straight line is the magnitude of the current required to produce a balancing magnetic field in the primary.

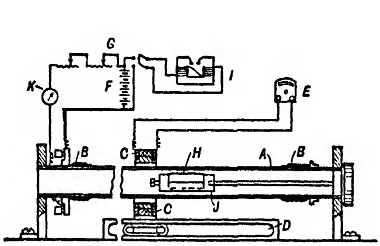

FIG. 130. Coercimeter.

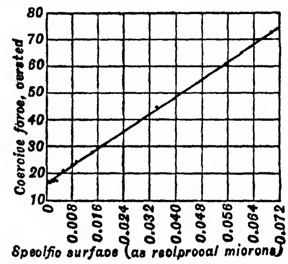

FIG. 131. Coercive force *vs.* specific surface for Mineville magnetite (*after DeVaney and Coghill*).

Linear dependence of coercive force upon surface area is shown in Fig. 131. Specific surface for this curve was calculated on the assumption of a spherical or cubic particle shape and does not represent direct measurement of surface area. Conversion of coercive force of an unknown powder to specific surface is made by determining the value on the specific-surface axis which corresponds to the measured value of the coercive force. This linear relationship is only exhibited by minerals having a zero or very low coercive force. Linearity is unaffected by small changes in packing density but does show a drift for large changes.

Limitations. The method is limited to the more magnetic mineral powders such as magnetite, ilmenite, pyrrhotite, franklinite, copper ferrite, magnesioferrites, and possibly chromite. ACCURACY cannot be evaluated from the existing data; REPRODUCIBILITY appears to be good. TIME required for a determination is about 10 min.

Specific Surface

Specific surface of powders may be calculated from the determined size distribution, if some assumption is made concerning the shape of the particles. The usual assumption is that the particles are spherical, whereupon the calculation proceeds as follows: (1) Calculate the number of spheres required to give the weight of material retained on some screen, assuming that the diameter of the sphere is the arithmetic average of the apertures of the passing and retaining screens. (2) Calculate the surface area of one sphere and multiply by number of spheres calculated in (1). (3) Repeat these calculations for all screen fractions and take the sum.

If the size distribution obeys a known distribution function, the calculation outlined may be shortened by an integration over the size range.

Bond method. For distributions obeying the Gaudin function (Art. 19), Bond (*A TP 1296*) gives the following method. The distribution functions are written in the forms

$$w = Bx^m \tag{72}$$

$$y = 100(x/L)^m \tag{73}$$

where w = % weight retained on screen with aperture x and passing the next larger screen, B = % weight retained on screen of unit aperture, L = aperture of top limiting screen, m = slope of distribution line developed by the log-log plot (see Art. 19), and y = cumulative % weight passing a screen of aperture x.

Take logarithms of both equations and subtract Eq. 72 from Eq. 73, whereupon $\log y - \log w = 2 - m \log L - \log B$. But if r = geometric size-scale ratio, *e.g.*, $\sqrt{2}:1$ for standard Tyler sieves, then, according to Schuhmann (*A TP 1189*),

$$L = \left\{\frac{Br^{-m}}{100(1 - r^{-m})}\right\}^{-1/m} \tag{74}$$

whence

$$Q = \log y - \log w = -\log(r^m - 1) \tag{75}$$

Values of Q for the usual range of values of m are given in Table 46.

Assuming spherical particles of diameter x, there are $\frac{6}{G_s \pi x^3}$ particles in a unit weight, hence the surface area per unit weight is $\frac{6}{G_s x}$, and for dy units of weight, the surface area is

$$dS = \frac{6}{G_s x}\, dy \tag{76}$$

Differentiating Eq. 73 and substituting its value for dy into Eq. 76

$$dS = \frac{600\, m}{G_s L^m} x^{m-2}\, dx$$

Therefore

$$S_2 - S_1 = \frac{600m}{G_s L^m (m-1)} x^{m-1} \Big|_{x_1}^{x_2} \tag{77}$$

which is the surface area of spherical particles between the two sizes x_1 and x_2 for a unit weight of original material. For 100 units of volume of material, G_s may be dropped from the denominator and dy represents percentage weight. Surface area per unit weight for material less than L units in diameter and greater than N units in diameter is

$$S = \frac{600m}{L^m(m-1)}(L^{m-1} - N^{m-1})$$

$$S = \frac{600m}{L(1-m)}\left(\frac{N^{m-1} - L^{m-1}}{L^{m-1}}\right) = \frac{600m}{L(1-m)}[(L/N)^{1-m} - 1] \tag{78}$$

Bond assumes, following Weinig (*28 CSMQ No. 3*), that a grind limit Z exists and assigns to it the value of 0.700μ, hence

$$S = \frac{600m}{L(1-m)}(\text{antilog}\,[(1-m)(\log L + 0.155)] - 1) \tag{79}$$

Example of Bond calculations. Plot the sizing analysis given in Table 47 on log-log paper. Two curves result, the w-curve (Fig. 132) when the figures in column 3, Table 47, are plotted as ordinates, and the F-curve when the figures in column 5 are plotted as ordinates. Draw a line of best fit (visually) for the w-curve. Determine the slope of the w-line, using two points, *e.g.*, (x = 0.09, w = 2.4) and (x = 0.9, w = 12), neither necessarily experimental, then

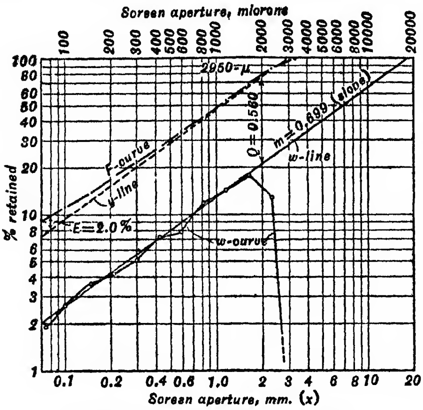

FIG. 132. Log-log plot for Table 47.

$$m = \frac{\log 12 - \log 2.4}{\log 0.9 - \log 0.09} = \frac{1.0792 - 0.3802}{1.9542 - 2.9542} = \frac{0.699}{1}$$

From Table 46 the value of Q is found to be 0.560. Determine the linear value of one cycle on the log-log paper (it was 2 3/4 in. on the original of Fig. 132). Multiply 0.560 by 2.75 = 1.54 in. and draw in a line parallel to the w-line displaced above it by 1.54 in.; this is the y-line. The intercept of the y-line with 100%-line is read off as 2,950-μ = L. The surface area in sq. meters for 100 cc. of material is calculated (Eq. 79) as

$$S = \frac{600 \times 0.699}{2950 \times 0.301} \left(\text{antilog}\left[0.301 \left(\log 2 \times 950 + 0.155\right)\right] - 1\right)$$

whence S = 5.3 sq. meters per 100 cc. of material. The vertical displacement E between the F-curve and the y-line denotes the amount of material originally present finer than the grind limit. When appreciable amounts of clay, etc., are present E is positive. When E is negative a natural grind limit, Z_1, other than 0.7-μ is indicated. This may be calculated from

$$\log Z_1 = \log L - \frac{2 - \log(-E)}{m} \qquad (80)$$

and the value obtained used in Eq. 78 in place of N. For other screen analyses of an ore for which a positive E-value is known, the F-curve may be plotted first and the y-line located thereby by displacement of E-units downward from the F-curve.

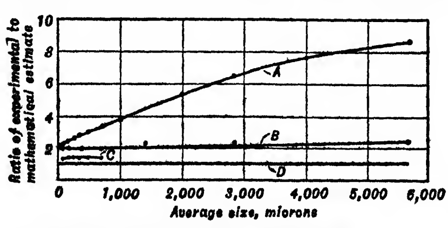
Significance of surface estimates. It is a little difficult to take these refinements in calculation seriously, for, at best, surface calculations based on sizing analyses are gross approximations. It appears that the distribution functions describe some observed distributions as closely, at least, as the size measurements approximate the truth, since sieve sizing, even with standardized screens, may be in error by 5%. The discrepancy between actual and calculable distribution at the coarse end of the size range is unimportant, because the contribution of the large sizes to the total surface area is negligible, within the accuracy set by other factors. The chief assumptions made are that particles are spherical, that there is a grind limit, and that distribution in subsieve sizes is linear and has the same slope as in the lower sieve sizes.



A Crushed quartz, hydrofluoric acid basis.
B Crushed quartz, silver basis.
C Ottawa sand, hydrofluoric acid basis.
D Mathematical estimate, based on assumption of spherical particles.

FIG. 133. Experimental *vs.* mathematical estimates of the superficial area of quartz.

It is probable that the superficial area of an aggregation of irregularly shaped particles is greater than the surface calculated on the assumption of spherical particles, but the ratio of these areas should be fairly constant if the particle shape does not change much with size. Gross and Zimmerley (*loc. cit.*), using the dissolution method for measuring surface, showed that the ratio of estimated to calculated surface area for Ottawa sand was fairly constant at an average

value of 1.34 : 1, over the range of 20- to 200-m. (Fig. 133), but that with crushed quartz it increased several hundred per cent. with increase in size, whereas with the silver-coating method, it was fairly constant at about 2. They attribute the high ratios by the dissolution method to cracks, penetrable by hydrofluoric acid but not by silver. Such cracks represent useful work done in crushing, because they are established surfaces of weakness in further comminution.

Weinig (*loc. cit.; 136 #7 J 336*) points out that the shape of particles changes with size and with method of breakage, hence the ratio of experimental results to those calculated on an assumption of invariable shape should not be constant. Weinig proposes a surface index, I_s, defined as

$$I_S = \frac{2 + R}{3} \tag{81}$$

where R is the ratio of the weight of a particle of given size assumed cubical to the actual weight. For example, 100 @ 10~14-m. particles are weighed and the weight W_1 per particle computed. The weight, W, of a cube of this size is $(0.145)^3$, hence $R = \frac{W}{W_1}$. The product of the surface index and the surface of a cube of this size, *i.e.*, $6I_Sx^2$ would give the probable mean surface for grain shapes other than cubical.

18. PARTICLE SIZE

Particles produced by crushing and grinding show an almost infinite variety of shape and size. No simple and accurate numerical expression of the dimensions of a single particle nor of the average dimensions of a group is possible; the best that can be done in any case is an approximation which is ordinarily expressed as a single number, as though the particles possessed some definite geometric shape. This number is called the DIAMETER or SIZE of an individual particle or the AVERAGE DIAMETER or AVERAGE SIZE of a group of particles.

Diameter of particle. The fundamental assumption of particle measurement is that the particle has three principal axes at right angles and that its dimensions are completely stated when the distances between the intercepts of the surface on the respective axes are given. Starting with this assumption, which is, on its face, only a crude approximation except in the case of materials with cubical cleavage, averaging of the three principal dimensions into a single figure is attempted by one of several different methods, as follows:

$$D = b \tag{82}$$

$$D = \frac{l + b}{2} \tag{83}$$

$$D = \frac{l + b + t}{3} \tag{84}$$

$$D = \sqrt{lb} \tag{85}$$

$$D = \sqrt[3]{lbt} \tag{86}$$

$$D = \sqrt{\frac{2lb + 2bt + 2lt}{6}} \tag{87}$$

$$D = \frac{3lbt}{lb + lt + bt} \tag{88}$$

where D = diameter and l, b, and t are respectively the distances between the intercepts of the surface on the long, intermediate, and short axes, or, in common parlance, length, breadth, and thickness of the particle. The significance of the first five approximations is immediately apparent; the sixth gives the edge of a cube whose total surface is equal to the total surface of a rectangular parallelopiped the dimensions of which are equal to the principal dimensions of the particle. The seventh is the harmonic mean of the dimensions. Green (*192 JFI 637; 204 ibid. 713*) develops the fact that this harmonic mean is a factor in the expression for specific surface. Thus, for a mass of spherical or cubical particles of the same size, $S_0 = 6/G_sD$, where S_0 = specific surface, G_s = specific gravity, and D = the diameter. But $S_0 = Ns$, where N = the number of particles per unit weight and s = the surface of each particle; whence, if the particles are taken as rectangular parallelopipeds, $S_0 = (1/G_slbt)[2(lb + lt + bt)] = 2(lb + lt + bt)/G_slbt$, and, by substitution in the first equation, $D = 3lbt/(lb + lt + bt)$. Which one of Eq. 82 to 88 is to be used in any given determination of particle size depends upon the method of measurement and the predilection of the experimenter. When screens are used, Eq. 82 is adopted perforce. When elutriation is employed without subsequent microscopic measurement of the fractions, Eq. 86 is necessarily involved. When individual particles are actually measured, any one of the seven assumptions may be employed, but Eqs. 83 and 85 are the ones most commonly used. When the Martin (*23 CerS 61*) statistical diameter is measured, Eq. 85 is preferred. Heywood (*56 CI 149*) showed that this diameter is closely related to the equivalent spherical diameter (*vide infra*) and evaluated a factor which when divided into the statistical diameter gives a close approximation to the equivalent spherical diameter.

For rounded sand particles it has a value of 1.05, for angular sand and crushed limestone particles the value is 1.3–1.45. Eq. 87 is no more accurate than Eq. 86 and involves much more computation, while Eq. 88 requires so much measurement and calculation, if a large number of particles is to be measured, as to be substantially impracticable.

Equivalent diameter (or NOMINAL, or EFFECTIVE DIAMETER) is a term used to describe an attempt to rationalize the infinitude of dimensions of an irregular particle. Such particles have definite volumes and surfaces, which, dimensionally and in a statistical sense, vary as the cube and square respectively of some linear dimension. This linear dimension is called the EQUIVALENT DIAMETER. When it is calculated from a measured volume, it designates the diameter of a sphere of equal volume and is, therefore, given by the equation

$$D_V = \sqrt[3]{6V/\pi} \quad \text{(EQUIVALENT SPHERICAL DIAMETER)} \qquad (89)$$

If it is calculated from a measured surface A, it designates the diameter of a sphere of equal surface and is given by the equation

$$D_A = 6/AG_s \quad \text{(EQUIVALENT SURFACE DIAMETER)} \qquad (90)$$

If it is based on the rate of fall in a fluid, it designates the diameter of a sphere of equal density and falling rate. If the rate is in the Stokes range, the equation is

$$D_S = \left[\frac{9}{2}\cdot\frac{vb}{g(G_s - G_l)}\right]^{1/2} \quad \text{(EQUIVALENT STOKES DIAMETER)} \qquad (91)$$

If the falling rate is in the Newton range, the equation is

$$D_N = v^2G_l/K(G_s - G_l) \quad \text{(EQUIVALENT NEWTON DIAMETER)} \qquad (92)$$

When the equivalent diameter is based on the projected area of the particle, it is referred to a circle having an equal area A_c and may be calculated by

$$D_c = \sqrt{4A_c/\pi} \quad \text{(EQUIVALENT CIRCLE DIAMETER)} \qquad (93)$$

Heywood (*56 CI 149; 140 IMechE 257; 125 ibid. 383*) has shown that for a wide variety of particles the equivalent spherical diameter is closely related to sieve aperture and equivalent Stokes diameter, being usually 5 to 15% larger. For excessively flat or elongated particles this relation fails. Table 48 shows the degree of correlation to be expected. Heywood also showed that the use of the equivalent spherical diameter is permissible if a correction factor is applied. Table 49 gives typical values of this correction factor calculated from his measurements.

Table 48. Comparison of equivalent diameters (*after Carman*)

Sieving		
Material	k [a]	D_V/x [b]
Copper shot	0.520	1.04
Coal, 10-m	0.227	1.12
Coal, 2-in.	0.326	1.08
Angular sand	0.258	1.11
Limestone, 10-m	0.315	1.00
Flake graphite	0.023	0.60
Mica	0.003	0.30

Stokes' law methods		Microscopic method	
k	D_V/D_s	k	D_V/D [c]
0.4	1.07	0.4	0.918
0.3	1.10	0.2	0.725
0.2	1.13	0.02	0.195
0.1	1.14	......	......

[a] k is a volume factor, such that $kD^3 = \pi D^3/6$, hence equal to $\pi/6 = 0.524$ for a sphere.
[b] x = sieve aperture.
[c] D = statistical diameter = mean projected diameter.

Table 49. Comparison of volume and surface factors (*after Carman*)

Material	k Volume factor [a]	ϕ Surface factor [b]
Sand (rounded particles)	0.34	0.81
Glass (angular particles)	0.28	0.65
Tungsten powder	0.45	0.89
Pulverized coal	0.25	0.73
Mica	0.03	0.28

[a] See Table 48, footnote *a*.
[b] $\phi = D_A/D_V$.

Shape measures of particles have been proposed by Wadell (*40 JG 443; 41 ibid. 310; 217 JFI 459*) who defines the degree of sphericity of a particle, ψ, as the ratio

$$\psi = S'/S \qquad (94)$$

where S' is the surface of a sphere which has same volume as the particle and S is the actual surface of the particle. Since the actual surface of the particle is usually impossible of measurement, Wadell developed the closely correlated measure of circularity C, which is defined as the ratio

$$C = c'/c \qquad (95)$$

where c' is the circumference of a circle having the same cross-sectional area as the particle, and c is the actual perimeter of the cross-section. Dimension C is also incapable of measurement in most cases.

Wadell has, however, shown experimentally that the ratio

$$\phi = D_V/D_c \qquad (96)$$

where D_V is derived from Eq. 89, and D_c is the diameter of the smallest sphere circumscribing the particle, is closely related to ψ. He found that for values of $\phi > 0.8$, $\psi = \phi$ approximately, and that for smaller values $\psi = \phi + 0.1$. These measures have valuable hydrodynamic characteristics. Table 50 gives values for the sphericity of various geometric bodies, and Fig. 134 gives the relation of Reynolds' number to drag for bodies of differing sphericities.

Table 50. Sphericities of some common geometric figures (*after Gaudin*)

Geometric figure		Sphericity
Sphere		1.000
Cube		0.806
Prism:	$a \times a \times 2a$	0.767
	$a \times 2a \times 2a$	0.761
	$a \times 2a \times 3a$	0.725
Disk:	$h = r$	0.827
	$h = r/3$	0.594
	$h = r/10$	0.323
	$h = r/15$	0.220
Cylinder:	$h = 3r$	0.860
	$h = 10r$	0.691
	$h = 20r$	0.580

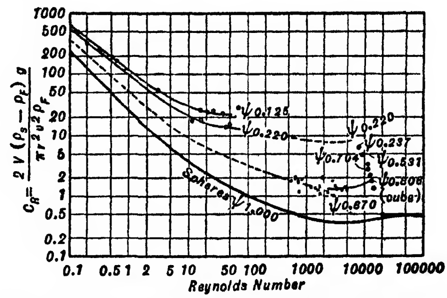


FIG. 134. Coefficient of resistance *vs.* Reynolds' number for solids of different sphericities (*after Wadell*).

Experimental determination may be made by taking photomicrographs of fields and projecting on such a scale that the diameters of circumscribed circles may be determined.

Particle-shape factors have been calculated by a number of workers. Martin *et al.* (*23 CerS 61*) have shown that the true volume V of a mass of irregularly shaped particles of nominal diameter D is proportional to $(\sqrt[3]{\Sigma nD^3/\Sigma n})^3$, Eq. 111; *i.e.*

$$V = K_V(\sqrt[3]{\Sigma nD^3/\Sigma n})^3 \qquad (97)$$

This relationship is not applicable to the individual particles. If the particles are spherical, $K_V = \pi/6$; for other materials $K_V < \pi/6$. Similarly the aggregate surface area A_S of a collection of particles is proportional to $(\sqrt{\Sigma nD^2/\Sigma n})^2$, Eq. 110; *i.e.*

$$A_S = K_S(\sqrt{\Sigma nD^2/\Sigma n})^2 \qquad (98)$$

For spherical particles $K_S = \pi$; otherwise $K_S < \pi$. Table 51 gives shape factors by Martin *et al.* and by Hatch and Choate (*207 JFI 369*).

Table 51. Particle-shape factors

e $[\Sigma nd^3/\Sigma n]^{1/3}$.

Projected area of particles. Faust and Cooke (*RI 3460*) describe a method for the rapid determination of the projected area of opaque particles. The method comprises (1) a measurement of the current I generated by a photoelectric cell where light from a uniformly illuminated field of area A is incident upon the photosensitive element; and (2) a similar measurement of photoelectric current I' when the illuminated area A' has been decreased by blocking out with opaque particles. The ratio of the currents is exactly proportional to the ratio of the illuminated areas, *i.e.*, $A'/A = I'/I = (A - A_0)/A$ and

$$A_0 = A(I - I')/I \qquad (99)$$

where A_0 = opaque area. Hence A_0 can be calculated from the measured values of I', I, and A.

Apparatus required is a microscope with transmitted light and a photoelectric cell. Faust and Cooke used an S-28 ocular photoelectric cell which can generate a current of 150 microamperes at 1,000 lux, adapted to the microscope so that the cell rested exactly above the eye lens of the ocular. A Leeds & Northrup type R moving-coil galvanometer was used with an external Ayrton shunt of 25,000 ohms. The sample was mounted on a slide in the usual manner (Art. 9), dispersed in a single-particle layer. The light source may be a 6-v. 32-c.p. automobile headlight bulb on a storage-battery, but uniformity of the field must be examined by placing an opaque object, perforated with a small hole, on the stage of the microscope and exploring the field. A large sub-stage condenser with a 4-v. bulb in a centerable socket is more satisfactory.

Procedure. (1) Place prepared slide on a mechanical stage and focus. (2) Locate a field in the mount which contains no particles, and note its co-ordinates. (3) Place ocular photoelectric cell in position and note galvanometer deflection d_1. (4) Locate a field containing opaque particles, count them, and determine the galvanometer deflection d_2 for the field. (5) Determine diameter of this field with a stage micrometer.

Calculation. Percentage of area blocked out by the particles $= 100(d_1 - d_2)/d_1$. Average single particle area $= \frac{100A}{n}\left(\frac{d_1 - d_2}{d_1}\right)$, where n = number of particles and A = field area calculated from measurement (5).

Accuracy. Faust and Cooke (*RI 3460*) tested the method by measuring the projected areas of calibrated screens and comparing with micrometric determination. Results are given in Table 52.

Time required to prepare slides, make the measurements and the photomicrographs, count grains and complete calculations is 3 to 4 hr. per sample.

Table 52. Comparison of screen apertures determined by projected areas and by micrometry

Screen, mesh	Micrometric calibration, μ	Ocular photoelectric cell calibration, μ	Factory markings, μ
150	108	108	104
200	74	75	74
270	56	58	53
400	35	36	38

Average diameter is calculated by some method of averaging the mean or equivalent diameters of a number of particles. Perrott and Kinney (*6 ACerS 417*) and Green (*204 JFI 637*) give the following summary of suggested methods:

Arithmetical mean	$D_A = (d_1 + d_2)/2$	**(100)**
Geometrical mean	$D_G = \sqrt{d_1 d_2}$	**(101)**
Laschinger's mean	$D_E = (d_1 - d_2)/(\log_e d_1 - \log_e d_2)$	**(102)**
Mellor's mean	$D_M = \sqrt[3]{(d_1 + d_2)(d_1^2 + d_2^2)/4}$	**(103)**
Mean of form	$D_F = 4(d_1^5 - d_2^5)/5(d_1^4 - d_2^4)$	**(104)**
Von Reytt's mean	$D_R = 0.435(d_1 + d_2)$	**(105)**
Number mean	$D_N = \Sigma nd/\Sigma n$	**(106)**
Length mean	$D_L = \Sigma nd^2/\Sigma nd$	**(107)**
Surface mean	$D_S = \Sigma nd^3/\Sigma nd^2$	**(108)**
Volume mean	$D_V = \Sigma nd^4/\Sigma nd^3$	**(109)**
Square-root mean	$D_B = \sqrt{\Sigma nd^2/\Sigma n}$	**(110)**
Cube-root mean	$D_C = \sqrt[3]{\Sigma nd^3/\Sigma n}$	**(111)**
Harmonic mean	$D_H = \Sigma n/[\Sigma(n/d)]$	**(112)**

where D is the mean diameter, d_1 and d_2 are the maximum and minimum mean particle diameters, respectively; d represents the successive mean particle diameters in a sizing operation, and n the numerical frequency of the corresponding d.

Formulas 100 to 104 are based on the assumption of an even gradation in size from maximum to minimum and necessarily also on an equal number of particles in each size group, or else they disregard the effect of frequency of occurrence of particles of the different sizes. Formula 105 is clearly an approximation to formula 100. Formulas 106 to 109 consider and weight the intermediate sizes on the bases, respectively, of (*a*) number of particles in the successive grades; (*b*) total length of mean diameters in these grades, *i.e.*, number of particles in a grade times mean particle diameter; (*c*) total surface, *e.g.*, number of particles in the grades times mean particle diameter squared; and (*d*) total volume, *i.e.*, number of particles times mean particle volume.

Eq. 106 has the physical significance that if the particles under investigation were laid side by side in a line and the length of the line was divided by the number of particles the quotient would be the number D_N. If the area covered by these particles was divided by the length of the line, the quotient would be the value D_L given in Eq. 107. On this base, the average height of a parallelopipedon equal in volume to the total volume of

Σn particles is the D_S of Eq. 108. Formula 109 is the equivalent of $D = \Sigma wd/\Sigma w$, where w = percentage weights of the different grades and the other letters have the significance already assigned. This is the formula commonly used when sizing is done by screens, sedimentation, or elutriation, and when the amounts of the various grades are determined by weight. Formula 110 gives the edge of a cube whose surface multiplied by the total number of particles in a given mass of particles is equal to the total surface of the mass, if the particles are taken as cubes. Formula 111 gives the edge of a cube whose volume multiplied by the total number of particles is equal to the total volume of the particles sized, considered as cubes. Formula 112 gives the harmonic mean of the diameters.

Comparison of methods. Perrott and Kinney (*loc. cit.*) give the microscopic sizing analysis shown in Table 53. Comparison of the average diameters calculated by the different formulas points clearly the uncertainty of meaning of this term and the necessity for stating the method of calculation when giving a numerical result. The result by formulas 100 to 105 is not affected in any way by the amounts

Table 53. Comparison of methods of calculating average diameter

Microscopic analysis

Diameter, microns (d)..	60	50	40	30	20	10	5	2

AVERAGE DIAMETER

	Formula	*Microns*
100.	$D_A = (d_1 + d_2)/2 = (60 + 2)/2$	= 31
101.	$D_G = \sqrt{d_1 d_2} = \sqrt{60 \times 2}$	= 11
102.	$D_E = (d_1 - d_2)/(\log_e d_1 - \log_e d_2) = (60 - 2)/(2.303[1.7782 - 0.3010])$	= 17.0
103.	$D_M = \sqrt[3]{(d_1 + d_2)(d_1^2 + d_2^2)/4} = \sqrt[3]{(60 + 2)(3{,}600 + 4)/4}$	= 38.2
104.	$D_F = 4(d_1^5 - d_2^5)/5(d_1^4 - d_2^4) = 4(60^5 - 2^5)/5(60^4 - 2^4)$	= 48
105.	$D_R = 0.435(d_1 + d_2) = 0.435(60 + 2)$	= 27
106.	$D_N = \Sigma nd/\Sigma n = (0.05 \times 60 + \cdots 81.8 \times 2)/100$	= 3.0
107.	$D_L = \Sigma nd^2/\Sigma nd = (0.9 \times 60 + \cdots 53.2 \times 2)/100$	= 7.0
108.	$D_S = \Sigma nd^3/\Sigma nd^2 = (7.8 \times 60 + \cdots 15.6 \times 2)/100$	= 21.0
109.	$D_V = \Sigma nd^4/\Sigma nd^3 = (22.4 \times 60 + \cdots 1.5 \times 2)/100$	= 36.4
110.	$D_B = \sqrt{\Sigma nd^2/\Sigma n} = \sqrt{(87 \times 60^2 + \cdots 155{,}000 \times 2^2)/(87 + \cdots 155{,}000}$	= 4.6
111.	$D_C = \sqrt[3]{\Sigma nd^3/\Sigma n} = \sqrt{(87 \times 60^3 + \cdots 155{,}000 \times 2^3)/(87 + \cdots 155{,}000)}$	= 7.6
112.	$D_H = \Sigma n/\Sigma(n/d) = 190{,}453/83{,}357$	= 2.3

in any of the grades. These formulas will, therefore, each give the same result for any mass of grains of mixed sizes, irrespective of the size composition of the mass, if, only, the largest and smallest particles are in every case of the same sizes. This fact condemns these formulas for anything but the crudest kind of work. Formulas 108 and 109 place too much weight on the coarser sizes and both they and No. 107 give results that have no real meaning in terms of the diameter of ideal particles which could be substituted for the actual particles. On the other hand, No. 108 is useful when specific surface is important, as is also Eq. 112. Results by formulas 106, 110, and 111 have the meanings already developed. Which of the three should be used in any given case is a matter of individual preference, since it is impossible to choose scientifically. No. 106 gives the easiest calculations and the physical significance is most readily visualised. It weights the finest particles most heavily and, therefore, gives an average that leans toward the fine end. No. 109 weights the coarsest particles most heavily and consequently the result leans toward the coarse end. No. 110 is intermediate between the other two and would, on that score alone, seem to be preferable. It is distinctly to be preferred when surface is the valuable property of the material.

Uniformity. The complete information regarding the texture of a mass of broken material is not expressed by the average size. Thus in Fig. 135 curves a, b, and c represent three possible sizing tests which indicate the same average size of material, but c, on account of the coarse material present, will appear coarser than either of the other two, whereas a, on account of the lack of fines, may appear coarser than b. Green (*loc. cit.*) gives the following equation from statistical mathematics for expressing the degree of uniformity as a coefficient

$$U = \Delta x\sqrt{n/2\Sigma f^2} \qquad (113)$$

where Δx is the difference between two successive values on the X-axis (size-axis), made equal to unity for convenience in calculation; n is the total number of particles measured, and f is the difference in units of length between the measured diameter of a given particle or group of particles of substantially the same size and the average diameter of the whole number of particles n.

Thus in Table 54, columns 1 and 2 represent the results of a particle count on a slide at a magnification of 20,000 diameters. Average particle size as measured at 20,000 magnification is

$$D_{(\times 20{,}000)} = \frac{\Sigma nd}{\Sigma n} = \frac{2{,}881}{276} = 10.44 \text{ mm.}$$

and $D = 0.522\text{-}\mu$. Column 4 gives deviations, in millimeters, at 20,000 magnification, between the diameters of the particles in the corresponding size groups and the mean diameter (*i.e.*, 10.44 less the number in column 1). Column 5 gives the squares of the numbers in column 4 and column 6 the product of columns 2 and 5. The total of column 6 is Σf^2 of the formula. The total of column 2 is n. Hence

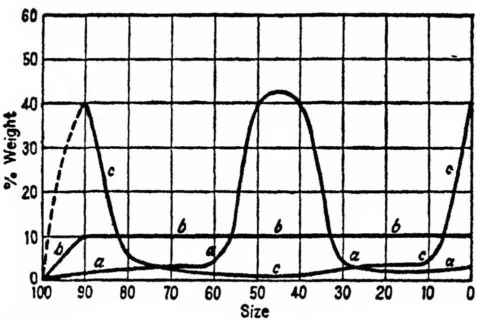

FIG. 135. Plots of three products showing the same average size $D = \Sigma wd/\Sigma w$.

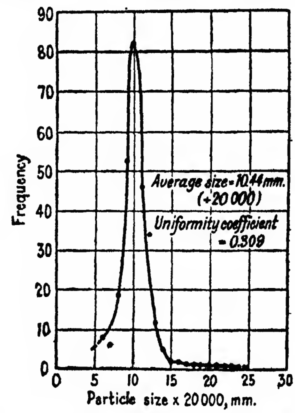

FIG. 136. Frequency plot of data in Table 54.

$$U = 1\sqrt{276/2(1{,}449)} = 0.309.$$

The uniformity coefficient ranges between 0, representing complete lack of uniformity, or no two particles of the same size, and ∞, which indicates all particles of the same size. The significance of the number 0.309, given above, is indicated by Fig. 136, which is a frequency plot of the data given in Table 54.

19. PRESENTATION OF SIZING TESTS

Sizing tests are made to (*a*) obtain quantitative information, or (*b*) investigate causal relationships in some operation or process under investigation. In the first case extent of conformity to some set specification is sought; in the second understanding to enable control and/or prediction is the end.

The general problem of presentation of data is soluble in terms of methods of analysis designed to extract from the raw data all of the essential information contained therein, in such form as is best suited to answer pertinent questions that may be posed concerning them. Complete solution to the presentation of sizing data is possible when an equation (distribution law) is known which accurately relates size or some function thereof to weight or some function thereof. Once the distribution law is known, any question of fact as to size may be answered in precise quantitative form.

Determination of distribution functions has been treated generally by Pearson (see p. 147), who showed that the function may be represented as a solution to a differential equation. This equation is applicable to size distributions normally found in mineral dressing, *i.e.*, the distribution contains only one maximum and vanishes gradually at the ends of the size range. Some size distributions possess the maximum and do not vanish gradually at the coarse end. When two maxima exist, one of them is very faint and may be neglected if a first approximation only is sought. Likewise, rapid vanishment of the function at the coarse end may be neglected in first approximation. There are, of course, an infinity of solutions to Pearson's differential equation; the choice made is dictated by the boundary conditions imposed. Of the many proposed solutions, the following appear to be most useful:

Normal probability function:

$$n = \frac{\Sigma n}{\sigma\sqrt{2\pi}}\, e^{-\frac{(D-D_{av})^2}{2\sigma^2}} \tag{114}$$

where n = the number of particles of size D, and σ = standard deviation. This is useful in some microscopic-sizing tests, but it is rarely obeyed. APPLICABILITY of the equation may be tested by plotting data on arithmetic-probability or logarithmic-probability paper, with size on the arithmetic or logarithmic axis and cumulative per cent. retained (or through) on the probability axis. If a straight line results this equation may be applicable to the data (see Fig. 137, item *K*).

Skewed probability function:

$$n = \frac{\Sigma n}{\log \sigma_g \sqrt{2\pi}}\, e^{-\frac{(\log D - \log D_G)^2}{2\log^2 \sigma_g}} \tag{115}$$

where D_G = geometric mean diameter and $\log \sigma_g$ = log-geometric standard deviation $\left(= \sqrt{\frac{\Sigma\,[n \log D - \log D_G^2]}{\Sigma n}}\right)$. This form is frequently met in microscopic sizing.

Hatch and Choate equations (*207 JFI 369*) are useful in calculating mean diameters. They are derived by means of the skewed function. They are

$$\log D_A = \log D_G + 1.151 \log^2 \sigma_g \tag{116}$$

$$\log D_B^2 = \log D_G^2 + 4.605 \log^2 \sigma_g \tag{117}$$

$$\log D_C^3 = \log D_G^3 + 10.362 \log^2 \sigma_g \tag{118}$$

These equations may be used to compute diameter of a grain having average surface area and average volume.

Rosin-Rammler function (*7 JIF 29*):

$$w_r = 100\, e^{-\left(\frac{D}{a}\right)^b} \tag{119}$$

where w_r = cumulative per cent. weight retained, D is the D_A from Eq. 100, and a and b are constants. This equation provides an excellent fit for size distribution of broken coal and relatively fine crushed ore. It has the advantage of a scientific basis, as its authors and Bennett (*10 JIF 22*) have shown. To test its applicability to a set of data, plot log (log $100/w_r$) against log of size; if a straight line results the equation holds (see Fig. 137, item *J*).

If the values of a and b for a particular material to which the Rosin-Rammler equation is applicable are known, the size distribution is completely specified. The constants a and b are best determined from the linear curve resulting from the Rosin-Rammler plot (Fig. 137, item *J*). Rearrange Eq. 119 thus: $100/w_r = e^{(D/a)^b}$. Then $\ln (100/w_r) = (D/a)^b$, and $\ln (\ln [100/w_r]) = b(\ln D - \ln a) = b \ln D - b \ln a$ (ln = Naperian logarithm). Let $\ln (\ln [100/w_r]) = y$, $\ln D = x$, and $b \ln a$ = a constant = c. Then $y = bx + c$, and b is the slope of the line, while $b \ln a$ is the y-intercept.

Further, if in Eq. 119, $D = a$, $w_r = 100e^{-(a/a)^b} = 100e^{-(1)^b} = 100/e = 36.8\%$, *i.e.*, a is that aperture which would retain 36.8% of the sample. This is called the ABSOLUTE SIZE CONSTANT. It is not the mean particle size by weight, surface, or length. DISPERSION CONSTANT, b, measures dispersion of material over the size range, since for small values of b, the size curve is close to the size-axis, and the material is spread over a wide size range; whereas if b is large, the curve is steeper and material is spread over a narrower range of sizes. Products naturally comminuted rarely have values of b less than 0.6. When b is about 3.0 the Rosin-Rammler function deteriorates and is best replaced by the Gaussian (normal probability) function.

Roller function:

$$w_t = a\sqrt{D}\, e^{-b/D} \qquad (120)$$

where w_t = cumulative per cent. through, and a and b are constants. To test for application to data, plot $w_t/\sqrt{D}$ on a log scale against reciprocal of diameter on an arithmetic scale; a straight line shows applicability.

Gaudin function:

$$w_r = aD^b \qquad (121)$$

$$w_t = 100(D/A)^b \qquad (122)$$

where a, b, and A are constants, w_r is the per cent. weight retained on screen with aperture D and passing next larger screen, and w_t is the cumulative per cent. weight passing a screen of aperture D. This equation has wide application but lacks the scientific basis of the Rosin-Rammler function. If a straight line results when cumulative per cent. through is plotted against size on log-log paper, the function is applicable (see Fig. 137, item G).

The significance of the constants in this function may be developed as follows: If D = one unit, $w_r = a(1)^b = a$, *i.e.*, a is the weight of material retained on the unit aperture and passing the next coarser aperture; it is a function of the particular unit of length chosen and of the sieve series used. Taking logarithms of the equation, $\ln w_r = \ln a + b \ln d$. Thus b is the slope of the linear curve obtained from the log-log plot (Fig. 137, item G) and $\ln a$ is the w-intercept.

The Gaudin function is usually applicable to a part of the data only, *i.e.*, to the finer sizes, hence b measures dispersion of material in the fine sizes.

The DERIVED GAUDIN EQUATION (Eq. 122) has two forms according to whether a lower size limit is postulated. If not, the form is as given (Eq. 122); with a lower limit

$$w_t = 100\,[(D/A)^b - (D_0/A)^b] \qquad (123)$$

where D_0 = the size limit. If the same mathematical analysis is applied to Eq. 122 or 123, it appears that A is the aperture of the upper limiting screen and b measures dispersion of material over the entire size range.

Comparison of Rosin-Rammler and Gaudin functions. For sizes below the absolute size constant, the two functions are identical. Thus the size distribution given in column 3 of Table 55 has been plotted in Fig. 137, items D, G, and J. The various approximately straight distribution lines indicate applicability. Values of the constants and size distributions, as calculated therefrom, are compared in Table 56.

Methods of plotting sizing tests. Fundamentally the graph of a sizing test portrays a relationship between particle sizes and the weights thereof in a mixture comprising grains of many sizes. Conventionally weight functions are plotted as ordinates and size functions as abscissae. Different types of graphs are characterized by the reference point from which weight is calculated, and by the functions of weight and size that are plotted. DIRECT plots are those in which the weight is referenced to the interval between screens, *i.e.*, the weight plotted at a given size is that of the material retained on the screen of that aperture and passing the next coarser screen. CUMULATIVE plots use either the finest screen or the coarsest screen as the reference. A CUMULATIVE-RETAINED graph plots against a given size abscissa the total weight (percentage) in the sample that is retained on a screen of that aperture; a CUMULATIVE-PASSING graph plots against a particular abscissa the percentage of the total sample weight that passes a testing sieve of that aperture. The usual functions of weight that are graphed are arithmetic and logarithmic percentages; special functions are plotted in Fig. 137, items *J*, *K*, *L*. The usual functions of aperture are arithmetic, percentage of limiting, reciprocal, and, occasionally, probability (item *K*). In designating types of

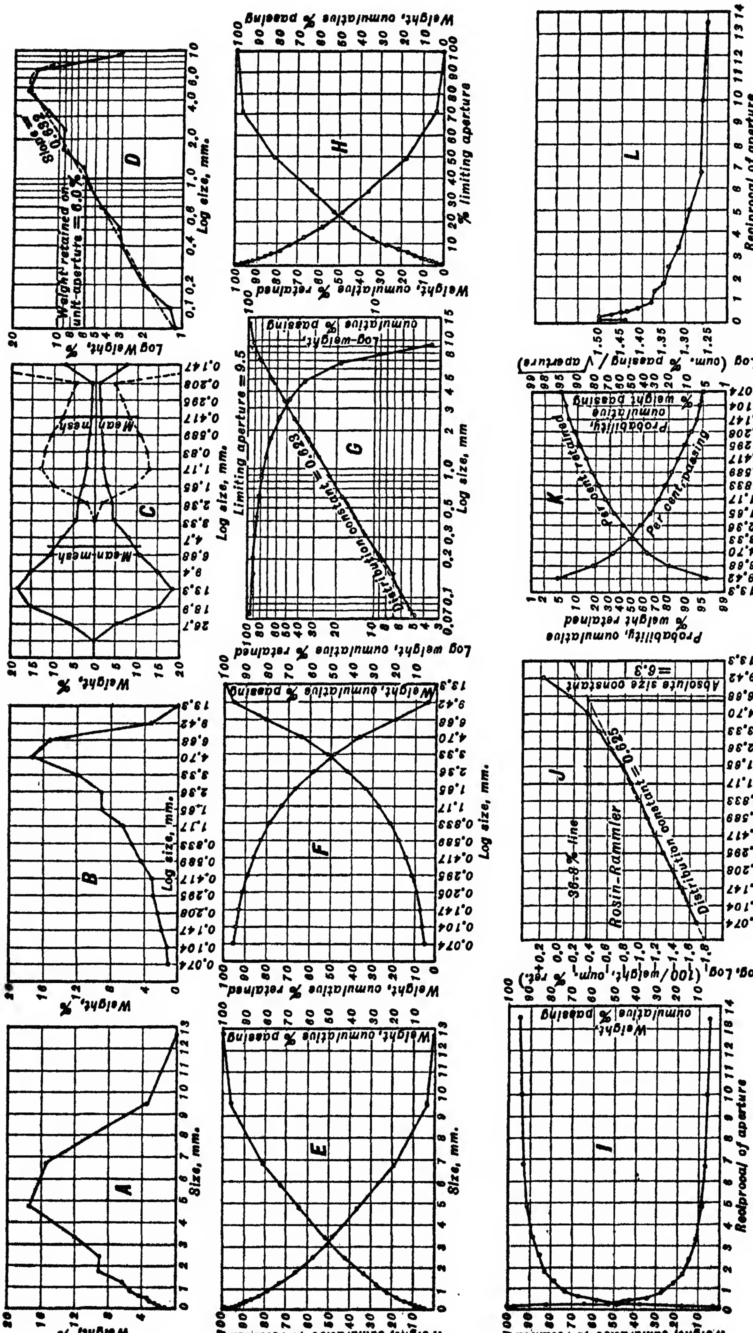

FIG. 137. Methods of plotting sizing tests.

graphs (see below) the characteristics of the ordinate precede the × sign; those of the abscissa follow. Common and some more unusual forms are shown in Fig. 137.

A. Direct, arithmetic both ways. The graph has the advantage of familiarity, but the fine sizes are so crowded as to make this portion of the curve practically meaningless.

B. Direct-arithmetic×log (single). Using screens with apertures increasing by a constant ratio, logarithms of apertures increase by a constant, hence abscissae of successive apertures are equally spaced along the horizontal axis. The curve necessarily terminates with the oversize of the finest screen, because of lack of knowledge of the size distribution of the undersize of this screen, and the fact that the logarithm of zero is infinity. Comparing items A and B, it is to be seen that the latter spreads out the fine part of the curve and compresses the coarse, so that distribution in the fine range is much easier to read.

C. Direct-arithmetic×log (mirror). This form was proposed by Coghill (*126 J 934*) as a means to aid visualization of the physical significance of a screen analysis, which it does. Otherwise it differs from form B only in that it assumes all of the <20-m. material to be of 0.147-mm. size for purposes of plotting. Comparison of curves for a feed (full) and for product (dotted) of a given comminuting operation gives a certain measure of the performance thereof. MEAN MESH is determined by the mesh or aperture (mm.) of the screen whose ordinal number $N_m = N_i W_i/100$, where N_i = ordinal assigned to the ith screen (number assigned to undersize of finest screen is that which would have been assigned to the next finer screen) and W_i = per cent. weight retained on ith screen and passing next larger screen.

D. Direct-log×log. This plot tends to straighten out the fine leg of the curve. It is used to investigate the applicability of distribution analysis of the Gaudin type.

E. Cumulative, arithmetic both ways. This graph reads directly at any point the total oversize and undersize of a given screen, but has the same disadvantage of crowding in the fine sizes as item A. The per cent.-passing and per cent.-retained curves are mirror images.

F. Cumulative-arithmetic×log. This graph has the advantages of both logarithmic and cumulative plots. The per cent.-passing and per cent.-retained curves are mirror images.

G. Cumulative-log×log. This method tends to straighten the per cent.-retained curve throughout its length. It is used as a test for applicability of the derived-Gaudin function. The per cent.-passing curve is not a mirror image.

H. Cumulative-arithmetic×per cent. limiting aperture. This graph is particularly useful in comparing screen tests of products in different size ranges, as, for instance, the discharges of a jaw crusher and of a ball mill. It reduces both ordinates and abscissae to the same scale, and all curves have common end points.

I. Cumulative-arithmetic×reciprocal aperture. This graph reverses the crowding of the direct arithmetic-aperture plots, and is useful to spread out the points when the amounts of fine material are small and of large material great, as in the case plotted. In the reverse condition, the curve becomes very crowded in the coarse end. Per cent.-passing and per cent.-retained curves are mirror images.

J. Cumulative-log log reciprocal×log. This is the plot for investigation of the Rosin-Rammler function (p. 145). The work involved in making the calculations for the plot can be reduced to a minimum by dividing the arithmetic axis of semi-log paper in proportion to log (log $100/w_r$) and marking each division with the value of w_r instead of the value of the logarithm. As an aid in the preparation of this paper, Geer and Yancey (*A TP 948*) prepared Table 57. The simplest method of

preparing the paper is to use the values given in the "difference" column (or some constant multiple thereof) to locate and mark points on the axis corresponding to the given values of w_r.

K. Cumulative-probability×log. This plot is made to establish the applicability of the normal-probability distribution law. The curve is straight when the distribution is symmetrical about some particular size.

L. Cumulative passing/$\sqrt{\text{aperture}}$-log×reciprocal. This plot has been used only in determining the applicability of the Roller function (see p. 146).

Frequency curves are plots in which, ordinarily, the number of particles of a given size, or some function thereof, is plotted against the size itself or a function. The simplest form is that of number against size (Fig. 136). Martin, Blyth, and Tongue (*Researches on the theory of fine grinding, Part I, British Portland Cement Research Association, Pamphlet No. 4, 1924*) plot increase in number of particles per unit increase in diameter ($\delta N/\delta D$) against diameter (D). In this curve any ordinate represents the rate of increase in number of particles at the corresponding value of particle diameter; the area between the curve, the X-axis, and any two adjacent ordinates is numerically equal to the number of particles between the corresponding diameters.

Callow method for graphical representation of screen analyses and sizing-assay tests is shown in Figs. 138 and 139 (*92 J 884*). Fig. 138 shows in block 1 a screen analysis of the product of a Dodge

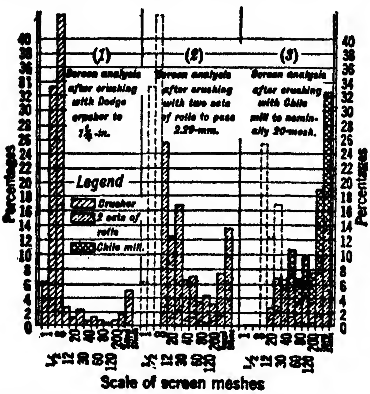

FIG. 138. Diagram of crushing performance.

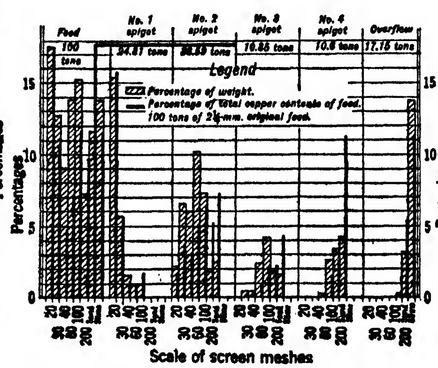

FIG. 139. Diagram of performance of hydraulic classifier.

crusher; in block 2 the product of two sets of rolls taking the material plotted in 1; and 3 shows the product of a Chilean mill fed with the roll discharge. The dotted rectangles in block 2 represent the coarse material that was contained in the roll feed which has been broken, and the dot-hatched rectangles in block 2 represent additions to the line-hatched rectangles of block 1. Similarly the open rectangles in block 3 represent coarse sizes in block 2 that have disappeared, and the cross-hatching represent fines produced from this material. This is an excellent picture, simple to construct. Fig. 139 pictures the products and performance of a hydraulic classifier showing both distribution of sizes and of valuable content. This likewise presents clearly data hard to comprehend from an array of figures. The method is applicable to any sizing-assay test.

GRAVITATIONAL TESTING

Gravitational testing deals with the differences in the motions in fluids of particles of different specific gravities. The theory is discussed and the processes are described in Secs. 8, 9, 10, and 11. Discussion in this section is confined to description of laboratory and/or pilot-scale apparatus and methods of procedure.

20. SINK-FLOAT SEPARATION

Sink-float separation (Sec. 11, Arts. 27, 28) is the simplest and most accurate method of gravitational separation available in the laboratory. It is used (*a*) to separate a material into its various specific-gravity fractions for determination of the amounts and characteristics thereof, (*b*) to separate an ore into its mineral components, (*c*) to isolate certain minerals or groups of minerals in one density range from other groups in another range, and (*d*) to check operating efficiency of concentrating or cleaning processes. When testing is directed toward investigation of mineralogical characteristics, heavy liquids are used; if the object is process testing, heavy suspensions.

Heavy Liquids

A complete series of liquids or solutions ranging in specific gravity from well under 1.0 to about 5.2 may be made or bought; intermediate densities of any desired value may be obtained by diluting or mixing the proper solutions in proper proportions. Sullivan (*TP 381 USBM*) reviews the field of heavy liquids, their properties and preparation in detail. The following is a brief description of the more commonly used liquids.

Bromoform ($CHBr_3$) is a highly mobile colorless liquid boiling at 149.5° C. and solidifying at 6 to 7° C.; its specific gravity is 2.890 at 20° C. referred to water at 4° C., but commercial bromoform rarely attains this density. It is completely miscible in alcohol, ether, and carbon tetrachloride, and quite soluble in benzene, chloroform, petroleum ether, and oils. Its complete miscibility with CCl_4 is utilized to produce solutions with densities ranging between 1.6 and 2.8. Sullivan (Table 58) gives the densities for the binary mixture, using commercial bromoform (sp. gr. = 2.61 at 25° C.) and carbon tetrachloride (sp. gr. = 1.58). Benzene is also used for dilution. RECOVERY of ingredients is accomplished by washing separated grains with the diluent and subjecting washings and used solution to fractional distillation. Fig. 140 gives the temperature coefficient of $CHBr_3$.

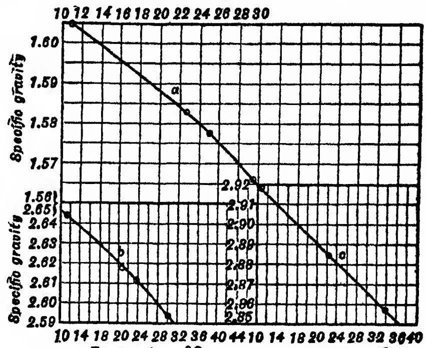

FIG. 140. Temperature *vs.* specific gravity (*after Sullivan*).

Table 58. Specific gravity *vs.* composition of bromoform-carbon tetrachloride mixtures

Per cent. $CHBr_3$ (by volume)	100	75	50	25	0
Specific gravity	2.61	2.35	2.09	1.84	1.58

Acetylene tetrabromide ($CHBr_2 \cdot CHBr_2$) is a colorless, mobile liquid at ordinary temperatures; it solidifies at 0.1° C., and boils at 151° C. at 54 mm. of Hg, and at 125° C. at 15 mm. of Hg pressure; at 20° C. it has a specific gravity of 2.964. It is soluble in water to the extent of 65 mg. per 100 cc. at 30° C., infinitely soluble in alcohol, chloroform, and carbon tetrachloride, and fairly soluble in anilin and acetic acid. Mixed with CCl_4, acetylene tetrabromide solutions vary in density from 1.6 to 2.9 as in Table 59. Fig. 140 gives the temperature coefficient of acetylene bromide and carbon tetrachloride in the room-temperature range. Recovery from solutions is accomplished by fractional distillation; C_6H_6 or CCl_4 may be used as wash liquid.

Table 59. Specific gravity *vs.* composition of acetylene-carbon tetrachloride mixtures

Per cent. $CHBr_2 \cdot CHBr_2$ (by volume)	100	75	50	25	0
Specific gravity	2.89	2.58	2.24	1.91	1.58

Stannic bromide ($SnBr_4$) melts at 31° C. to a colorless liquid with a specific gravity of 3.34 at 35° C. In the liquid state it is completely miscible with CCl_4; in the solid state it is soluble in acetone and in cold water (attended by gradual decomposition); it is decomposed immediately by hot water. Mixed with CCl_4, solutions with specific gravities ranging from 1.58 to 3.35 are obtained (see Table 60).

Table 60. Specific gravity *vs.* composition of stannic bromide-carbon tetrachloride solutions

Per cent. $SnBr_4$ (by weight)	100	73	49.5	37.5	0
Specific gravity	3.334	2.58	2.14	1.91	1.58
Temperature, °C.	35	22.3	23.0	24	25

Mineral particles may be washed free of $SnBr_4$ by CCl_4, and recovery effected by evaporation or fractional distillation. Metallic sulphides when dry are unaffected by $SnBr_4$ but when wet are attacked; stibnite is acted upon slowly.

Preparation. Sullivan gives the following method: Place powdered or granular tin in a distilling flask fitted with a reflux condenser. Fit a two-hole rubber stopper in the top of the condenser. Pass the stem of a dropping tube filled with bromine through one hole and the connecting tube of a $CaCl_2$ drier through the other. Add bromine drop by drop until reaction is complete; then drive off excess bromine by distillation, and finally distil the bromide. The distillate crystallizes into snow-white crystals having a m.p. of 31° C. and a b.p. of 203° C.

Antimony tribromide ($SbBr_3$) is a white crystalline compound melting at 96.6° C., boiling at 280° C. with a gravity of 4.148 at 23° C. It is decomposed by water; is soluble in absolute alcohol, acetone, bromoform, carbon tetrachloride, and is infinitely miscible in the liquid state with liquid stannic bro-

mide, giving with the latter solutions ranging in gravity from 3.11 to 3.6 (see Table 61). Antimony bromide-stannic bromide solutions are RECOVERED by washing with alcohol, acetone, or CCl_4, and separating from the solvent by fractional distillation.

Table 61. **Specific gravity *vs.* composition of antimony tribromide-stannic bromide mixtures**

Gravimetric % $SbBr_3$	100	72.2	50.8	24.8	0
Specific gravity	3.64	3.45	3.38	3.26	3.11
Temperature, °C	108	108	107	108	108
Freezing point, °C	94.2	82	77	71	30

Preparation of $SbBr_3$ parallels that given for $SnBr_4$. Caution should be exercised in addition of bromine to Sb, as the reaction is very vigorous and is accompanied by evolution of heat and light.

Thallium formate (TlCOOH), sp. gr. 4.95 at 105° C., m.p. 94° C., is prepared by treating Tl_2CO_3 with $Ba(COOH)_2$. To prepare thallium carbonate Clerici (*16 Rend. Accad. Lincei 187; 31 ibid. 116;* also Vassar, *10 Am. Mineral. 123*) placed thallium turnings in a shallow dish with not enough water to cover them. After 24 hr. more water is added, heat applied, and the solution filtered and allowed to crystallize. This procedure is repeated until the metal is exhausted. Water solutions of this salt give solutions with gravities ranging from 4.95 to 1.0 (see Table 62). RECOVERY is effected by washing with water, whence the TlCOOH may be recovered by evaporation.

Table 62. **Specific gravity *vs.* composition of thallium formate solutions**

Gravimetric % TlCOOH	100	95	90	85	80	75
Specific gravity	4.95	4.19	3.72	3.39	3.09	2.86
Temperature, °C	105	60	42	25	25	25
Melting point, °C	94	54	31	22	.....	.....

Thallium formate-malonate. A mixture of thallium formate and thallium malonate was found by Clerici to give higher specific gravities than the formate alone at the same temperature. The best results were obtained with a mixture of 10 parts formate, 10 parts malonate, and 1 part water; this mixture is odorless, colorless and extremely fluid and can be recovered by evaporation. Seven grams each of formate and malonate completely dissolved in 1 cc. of cold water; 10 grams of each leaves some undissolved solid and the filtrate has a sp. gr. of 4.067 at 12° C. Formate alone gives this sp. gr. only at 45° C. and the malonate only at 60° C. By further additions of formate-malonate a sp. gr. of 4.40 is reached at 35° C. and of 4.65 at 50° C.

Antimony trichloride solution of a eutectic $HgCl_2$-HgI_2 mixture gives sp. gr. ranging from 3.44 at 121° C. for a 1 : 1 solution, through 4.05 at 145° C. for a 3 : 1 solution of $SbCl_3$: $HgCl_2$-HgI_2, to 4.55 at 135° C. for a solution containing 87.5% HgI_2-$HgCl_2$. All three components are soluble in anilin, which may be used to wash particles. This solution decomposes sulphides, hence is limited in applicability to nonsulphides.

Procedure in testing with heavy liquids consists essentially in immersing the powdered mixture in a suitable solution, diluting until the desired constituent or constituents sink, separating the floating from the sunken portion, separating the solution from each portion, and washing the solid until free of solution. It is preferable to have mineral particles dry, otherwise dilution of the heavy liquid may occur; if the heavy solution is decomposed by water, *e.g.*, $SbBr_3 + CCl_4$, the particles must be dry. Drying is best accomplished by washing with acetone. When the heavy liquid must be used at higher than room temperatures a water or steam bath is practical for temperatures below 100° C. and an oil bath for higher temperatures. *Johannsen* describes a large number of separating vessels, chiefly applicable to close separations of a number of constituents. Tomlinson (*52 A 852*) described a method of mineralogical analysis of sand that is adaptable to most ore-dressing work.

Preparation. Dry. Size carefully and record weights of grades. Apart from the information thus obtained, sized products are more accurately separated in heavy solutions than unsized.

Separation, especially of <48-m. material, is most readily made in a Harada or similar tube, which is a special separatory funnel (see *Johannsen*), but it may be made satisfactorily in beakers. Use a beaker with capacity about six times the volume of the lot of sand to be separated, dry it thoroughly, add the solution (two volumes of solution of proper density to one of sand), stir in the sand slowly, allow it to stratify, skim the bulk of the float, then pour off some of the liquid with the balance of the floating material. Some floating sand will usually stick to the beaker in pouring off. If so, push it away on the sides of the beaker with a glass rod until sufficient clear space is available to pour out the settled solid with the balance of the liquid without contamination. Wash the separates repeatedly with water or other suitable diluent to remove and save solution. If several grades are to be made, it may be well to separate first at an intermediate density and rework the rough grades at higher and lower densities respectively, making sure that they are thoroughly dry before retreatment.

Separation of < 150-m. material is effected by centrifuging to increase sedimentation rate. The technique consists in charging the centrifuge cups with solution and sample and centrifuging for some predetermined time. The float together with solution is removed by pipetting to within some fixed distance from the sediment. Float and sink may be cleaned and recleaned by repetition of this operation, depending upon the accuracy desired, microscopic observations being used for check purposes

Sink-float test for coal. Coal analysis is the most important application of heavy-liquid testing. Any of the solutions and the method described may be used, but the volume of sample is usually so large and the coal so light that special methods and cheaper solutions are normally employed. The method is particularly suitable because with any given coal the ash content has a direct and substantially constant relation to the specific gravity, so that once an allowable ash content for a coal has been set, and the specific gravity of the highest-ash particle therein has been determined, a solution of that specific gravity will float good coal and everything that sinks will be of higher ash content than the permissible limit. The specific gravities of the usual impurities associated with coal compared with those of coal are shown in Table 63. It is apparent that a heavy solution of specific gravity between 1.50 and 1.65 would put all of the distinct impurities and some of the bone coal into the sink fraction. With different coals the ash content and the specific gravity have distinctly different relations, as is shown in Table 64; hence the necessity to establish the ash-specific gravity relation and the critical specific gravity for each coal.

Table 63. Specific gravities of common ingredients of raw bituminous coal (*after Drakeley*)

Material	Specific gravity	
	Range	Average
Coal..................	1.17 to 1.35	1.30
Bone..................	1.35 to 1.65	1.50
Carboniferous shale......	1.65 to 2.15	1.85
Shale..................	2.15 to 2.55	2.40
Coal or shale with pyrite..	2.55 to 4.80	3.65
Pyrite.................	4.80 to 5.20	5.00
Quartz.................	....	2.60
Calcite................	....	2.71+
Feldspar...............	....	2.40

Solutions. The usual heavy solution for coal testing is a water solution of zinc chloride. This gives a maximum density of about 1.80 at ordinary temperature. Calcium chloride is sometimes used. Sinnat and Mitton (*67 IME 494*) used mixtures of carbon tetrachloride (sp. gr. 1.582 at 21° C.) and toluene (sp. gr. 0.8708). For sizes finer than 20-m. McMillen and Bird (*Bul 28 UW Ser. 61*) used a mixture of carbon tetrachloride with benzene or bromoform, according to whether densities below or above 1.58 were desired. Willis (Du Pont *PC*) used mixtures of acetylene tetrabromide and pentachlorethane for gravities above 1.678 and a solution of the latter in a light petroleum distillate for lower specific gravities.

In changing solution strengths, the volume x of old liquid to be withdrawn and new solution to be added may be calculated by the equation, $x = (O - N)V/(O - A)$, where V is the volume of testing solution before and after the change in density, and O, N, and A are the specific gravities of the old, new, and added solutions respectively. If the testing tank is of constant cross-section, x and V may be expressed in units of depth of liquid in the tank, if there is no appreciable amount of solid material in the tank.

Table 64. Relation between specific gravity and ash content of various Vancouver coals (*after Garman*)

Order of increasing ash *a*	Clean coal		Refuse	
	Specific gravity	Ash, %	Specific gravity	Ash, %
1	1.30	3.86	1.76	42.22
2	1.25	3.90	1.57	44.37
3	1.32	7.12	1.91	57.13
4	1.28	7.50	1.75	62.25
5	1.24	7.63	2.00	68.50
6	1.60	8.22	1.77	75.34
7	1.30	9.00	2.25	84.55
8	1.31	15.57	2.60	88.38
9	1.38	17.55	....	....
10	1.43	26.25	....	....

a There is no necessary relation between the clean coal and the refuse in any given horizontal line; they may not be from the same coal.

Size of sample depends on the size of the particles. McMillen and Bird (*loc. cit.*) recommend 500 lb. for egg-size coal (3~1 1/2-in.); 250 lb. for nut-size (1 1/2~3/4-in.); 125 lb. for pea (3/4~3/8-in.); 50 lb. for buckwheat (3/8~3/16-in.); 25 lb. for birdseye (3/16-in.~20-m.); and 0.5 lb. for <20-m.

Apparatus. The essential elements of the apparatus for making tests conveniently are a container large enough to hold the sample and means for removing the sink and float fractions separately.

Fig. 141 represents an apparatus for coarse sizes developed by the U. S. Bureau of Mines. It consists essentially of a wood or zinc-lined tank *a* and two perforated-bottom containers for removing the separated fractions. The sink pan *b* rests on the bottom of the tank and has a permanent perforated bottom and handles at the end. The float rim *c* rests on the upper edge of the sink pan. As set into place for a test, it is merely a 4-sided rim extending the sides of the sink pan above the surface of the liquid in the tank. After the charge has separated into sink and float fractions, a flexible screen *d* is slid down through and along the groove (*e*, *e*, *e*) in the float rim until it forms a perforated divider between the fractions and a support on which to lift out the float fraction when the float rim is removed. Details of construction are shown in the figure.

Procedure, especially when the feed contains impurities that disintegrate in water, is to start with the heaviest solution (1.70 sp. gr. for bituminous coals and 1.80 for anthracite will float all material of any value). The sample is shoveled into the assembled apparatus, float being skimmed as necessary to maintain the layer of float at not more than three particles deep. It is necessary to make certain, before any material is skimmed, that the specific gravity of the solution is exactly that or less than

that at which separation is intended. Float should be stirred before skimming to prevent removal of entangled sink material. When all of the sample is in, the specific gravity of the solution should be brought to exactly the desired figure (using an accurate hydrometer for testing), the sink should be stirred to free any entangled float, and then the screen inserted into the float rim (Fig. 141) and the latter lifted out and placed on a suitable draining board arranged to collect drippings. The sink should

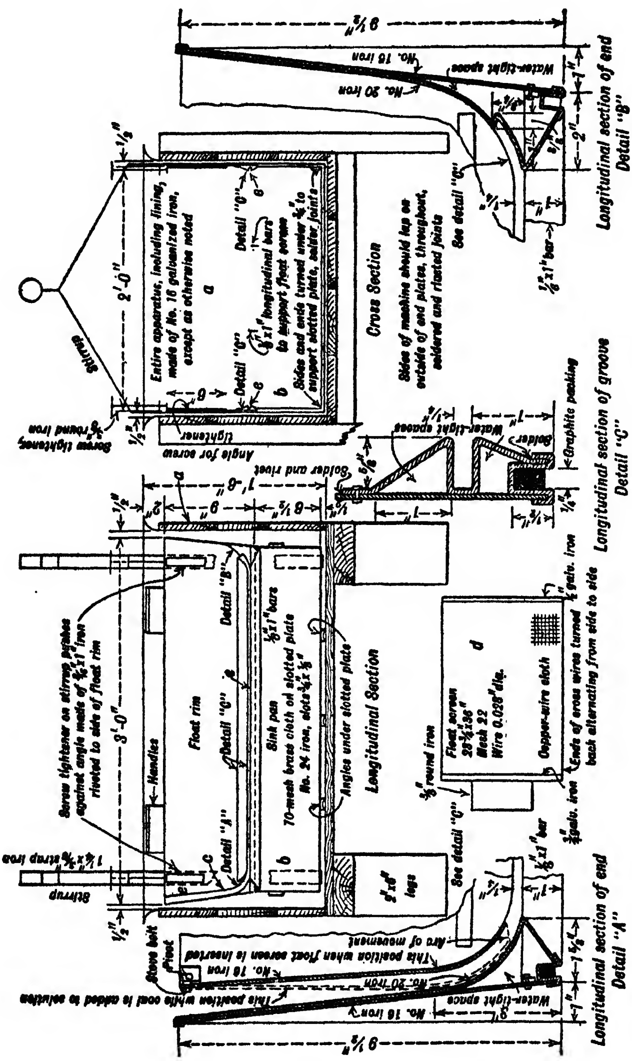

FIG. 141. Apparatus for sink-float testing of coal.

then be removed, drained, washed free of heavy liquid, and dried. Next reassemble the apparatus, dilute the solution to the next lower separating density, and retreat the preceding float. Repeat until the desired number of cuts has been made.

Fine material. For material finer than 20-m. a two-liter bottle makes a good separating container and carbon tetrachloride with benzene or bromoform good heavy solutions. Float material may be drawn into a two-liter vacuum flask by means of a glass tube. Separating solutions must be maintained at constant temperature in order to maintain constant specific gravity. The sample should be 200 gm. of air-dried (105° C.) coal which has been thoroughly wetted before separation. Twenty-four hours may be required for complete separation. The specific gravity of the solution must not be adjusted during a given separation.

TESTS OF MACHINES AND PROCESSES

The ultimate purpose of testing in commercial mineral-dressing operation, whether custom or plant, is usually one of the following: (*a*) to devise a flowsheet for the treatment of a particular crude; (*b*) to improve the operation of a part of an existing flowsheet; (*c*) to investigate the behavior of a particular machine or process, either on a given material or on materials generally; (*d*) to instal and maintain controls on particular machines and/or on an operation as a whole; (*e*) to devise new machines and processes, or novel modifications of old ones. In noncommercial laboratories, investigation is usually directed toward explanation.

21. TESTING FOR A FLOWSHEET

The essential steps in testing for a flowsheet are (1) determination of the nature of the crude, particularly as regards the kind, quantity, and distribution of valuable constituents, and (2) subjecting it to tests by methods which experience indicates give the best promise of optimum beneficiation at minimum operating expense.

The successive steps in an ore test vary with the ore, the extent and thoroughness of the campaign, and with the individual predilections of the investigator, but in general they should always comprise: (*a*) accreditation of the test sample; (*b*) preliminary tests directed toward the determination of the mineralogical composition and structure of the ore; (*c*) process tests on suitably prepared parts of the sample.

Accreditation of the sample should be the first step in every ore-testing campaign. The investigator should have some personal knowledge of the extent to which the sample is representative of the deposit from which it purports to come; failing this, responsibility for its character should be definitely placed, in writing, and subsequent reports of tests, and recommendations based thereon, should be made subject to such accreditation in clear and unmistakable language.

Weight of sample. Preliminary tests can be made using not more than a few pounds of ore—an amount sufficient for microscopic tests, assays, and, if indicated, two or three panning and flotation tests or the like. A sample weighing from 50 to 1,000 lb. should be available if any extensive process testing is contemplated; more is necessary for gravity concentration tests than for flotation or simple cyanidation.

Sampling methods vary with the character of the ore. Accurate sampling is necessary both in taking the original test batch from the deposit and in taking lots from the test batch for the various laboratory tests. For principles and methods of sampling deposits of crude see *Peele;* for methods of sampling batches see Arts. 2 and 3.

Preliminary testing. The first step, assuming that the investigator starts from scratch on a sample of interesting-looking but unknown ingredients, is determination of mineralogical composition. This is best done by an expert mineralogist, but may be done, with less expedition and assurance, in the mineral-dressing laboratory. If the general character of the valuable constituent or constituents is known, investigation should start with an assay of a representative sample. This assay, taken in connection with the location of the property and available data on extraction costs, markets, etc., will determine whether further work is justified.

Subsequent steps depend upon the character of the ore. If this is an industrial (nonmetallic) mineral, the size of the marketable product may be a controlling factor, in which case concentration, if it is to be practiced, must be subordinated to the limitations thus imposed. With industrial minerals not subject to size limitations and with metalliferous ores, the next step is to determine the size distribution of the valuable mineral. Macroscopic study of the sample and microscopic examination of selected lumps are the usual preliminary methods for such determination. If these studies indicate that valuable mineral or gangue may probably be freed at sizes coarser than 10-m., this indication is usually checked and roughly quantified by a sizing-sorting-assay test (see p. 157). If fine grinding is required to free the values, the sizing-sorting-assay test may be omitted, and preparation for detailed testing may properly start as soon as this fact is determined.

Preparation for process testing means essentially performance of the steps necessary to obtain a representative sample for the test. The sample must be representative, both as to composition and particle-size distribution, of the material that might be expected to go to the particular machine or process in a mill built to treat the ore in question. Such a sample may be secured by subjecting the original material or a sample thereof to a sequence of steps similar or equivalent to those to be expected to be used in such a mill prior to the machine or process under consideration. This requires that a qualitative

flowsheet of such a mill be drawn up and that a test flowsheet, substituting suitable laboratory equivalents for the proposed mill steps, be prepared and followed. If fine grinding is indicated, the preliminary preparation simply involves crushing by any means (not involving the introduction of too much metallic iron) to a maximum size suitable for grinding to final size in the laboratory ball mill. If, on the other hand, the prevailing mineral aggregation is coarse enough to justify a trial of gravity methods of concentration or if the process under test is a gravity process, it may be desirable to carry on the crushing in such a way as to minimize production of fines.

Time, as a factor in chemical reaction, is an essential element in some flotation operations, in that oxidation of metallic sulphides is a necessary preliminary for reaction with chemical collectors. But heavy oxidation results in large consumption of collector and may cause activation of the gangue minerals. Consequently sulphide ores should never be ground to flotation size until immediately prior to the flotation operation; they should not be crushed to a size that will free much sulphide mineral and then allowed to stand for long periods before use. If they are particularly subject to oxidation, as, for example, highly pyritic ores frequently are, they may be expected to oxidize sufficiently even as, say, <2-in. crusher product, in standing around for periods of several months, to cause difficulties that would not ordinarily be met with in a mill treating the same ore freshly broken in the mine. Conversely, if it is practice at a particular mine to let broken ore lie in the mine for weeks or months before milling it (large shrinkage stopes, caving, etc.), the ore tested should not be freshly broken, unless it has been demonstrated that no sensible change occurs during the broken-storage period.

Samples for flotation testing should never be wetted and dried before treatment, and pulp samples taken from an operating mill should be floated immediately. Likewise the sample cutter and container should not be of materials which could introduce into the sample ions unusual to the circuit.

Process ranges. Testing should start with those methods which practice teaches are most likely to be applicable; processes commercially unproved should be tried only after tested methods prove unfeasible, and should never be recommended for adoption unless ample funds are available for process development. Flotation and/or gravity concentration will treat the great majority of mineral crudes successfully; magnetic separation is pre-eminent in a limited field; beyond these is a short miscellaneous list, *e.g.*, electrostatic separation, differential grinding, decrepitation, and thermochemical conditioning to render certain minerals amenable to one or another of the foregoing standard treatment processes, each member of which has a record of scattered and relatively unimportant commercial applications.

Chemical methods for the treatment of crudes are manifold in detail but few in principle. All depend upon preferential chemical response of the constituents of the crude mineral, of such nature as to change the desired constituent into a phase different from that in which the residue exists; whereupon separation of the phases is effected. The principal classes of such process are: water leaches, chemical leaches, and chemical transformation followed by leaching, in all of which the desired ingredient in a liquid phase is separated from a residue which may be either liquid or solid. Other classes are roasting, calcination, sublimation, distillation (wherein one ingredient is vaporized and then led away from the residue which is liquid or solid), liquation (wherein one ingredient is liquefied and led away from a solid residue), and smelting (wherein the entire mass is changed into a mixture of immiscible liquids by heat and chemical action, and these, after stratification, are drawn off separately). Subsequent refining of the impure separates thus obtained involves further applications of the same types of method; plus precipitation, in which a selected part of a mixed fluid phase is rendered solid (or immiscible liquid) and separated by sedimentation, filtration, or the like.

Gravity concentration is most widely applicable. It is effective in the absence of slimes at sizes from 325-m. to 20-m., and, irrespective of the presence of slimes, at all sizes from 20-m. to the coarsest at which mineral is free, provided only in both cases that the concentration criterion is large enough (Sec. 11, Art. 1). If the concentration criterion is less than 1.5, close and careful work is necessary, if standard methods are to be used, and normal standards for cleanliness of concentrate and for recovery must be abandoned.

Sink-float separation is gravity concentration in a fluid or semifluid heavier than water. Use of such a liquid has the effect of increasing the concentration criterion of the minerals to be separated; in the limiting case, which is that usually practiced, the criterion becomes infinity when the density of the medium becomes equal to or less than that of the lighter mineral. Semifluids made by suspending fine solids in water by agitation (Chance and MBI processes, Sec. 11, Arts. 28, 29) have had considerable use; heavy liquids, organic and aqueous salt solutions, have not been used commercially. The method is readily applicable to sizes from about 3/8-in. up to head size; sizes down to 10- or 14-m. are treatable in some cases; finer sizes will not, at present, separate satisfactorily.

Air separation, as a concentrating means, is a form of gravity concentration applicable to closely sized granular materials, preferably of relatively low specific gravity, such as coal and slate, which are treated commercially in sizes up to 2 in. It will make some separation of gold from gravels. It has been used for some very close separations, *e.g.*, of garnet from associated minerals, and is reported by sellers of dry-concentration apparatus to have wide application in such service, but operating data

are scarce for separations other than coal-slate. In general, it is used only when the cost of water is prohibitive. (See Sec. 11, Art. 35.)

Washing, in one of its various forms, is applicable whenever great differences in size or shape exist between the minerals to be separated; or when there is a workable concentration criterion and high tailing can be tolerated. Thus washing on screens is commonly used to separate clay and fine sand from coarse material such as gravel, pebble phosphate, shell, crushed limestone for shaft kilns, etc.; log washers are used in similar service when more forcible disintegration is required; and washing in classifiers and the like is used for fines rejected by coarse-washing and scrubbing operations (see Sec. 10).

Flotation, in the usual froth-flotation sense, is applicable at 35-m. as a maximum, and not highly efficient at sizes coarser than 65-m. As a rough scalping process for light minerals, such as coal, froth flotation has been operated on <10-m. feeds; and a modification involving preliminary desliming and the levitation of clotted air-mineral aggregates will operate on certain minerals of gravities between 2.5 and 3 (*e.g.*, phosphates) in mixed sands up to 6- or even 4-m.

It is probable that any mineral which contains a distinctive element or radical, capable of being ionized in aqueous solution at the mineral-particle surface, can be floated away from any other mineral or group of minerals not containing the same characteristic constituent. But it must be recognized, as a practical matter, that unless the mineral that it is desired to float falls within one of the classes for which suitable conditioning agents and collectors are presently known, finding a flotation method probably involves long and arduous research and is not a simple ore-testing problem.

The minerals of known amenability to flotation collection at present are: native elements such as sulphur, gold, graphite, platinum, and copper; simple salts, such as the metalliferous sulphides, tellurides, and the like, the halogen salts of heavy metals, alkali earths, and alkalis, the carbonates, sulphates, and phosphates of the heavy metals and alkali earths, and amphoteric salts of heavy-metal and alkali-earth bases, such as molybdates, tungstates, and vanadates; quartz and some of the simple salt-type silicates; and the solid carbonaceous minerals like gilsonite, anthracite, and bituminous coal. On the other hand the metallic oxides, *e.g.*, hematite, cuprite, cassiterite, bauxite, magnetite, ilmenite, rutile, corundum, etc., and the oxide solid-solution type of silicate mineral, have thus far resisted successful collection in plant-scale operations.

Magnetic separation is supremely applicable to the separation of magnetite, franklinite and ilmenite, at all sizes at which these minerals are freed, from fine sands up to sizes where hand sorting becomes more profitable. It may also be used to separate the minerals of the weakly magnetic group listed in Table 1, Sec. 13, and high-iron garnets from the nonmagnetic group, but for such treatment the feed must be finely granular and dry, and expensive high-intensity low-capacity machines must be employed.

Miscellaneous methods, previously mentioned, are specials. Until they are better established commercially, they should not be tested on an ore unless all standard methods have failed, the economic reward for success is great, highly intelligent operation is assured, and the client can stand probable loss. The one exception to these restrictions is electrostatic separation, on which a great deal of experimental and small-size commercial work has been done, and for which some reasonably dependable plant performances are probably available.

Process testing. If microscopic and chemical tests on the crude indicate the probable applicability of standard methods of treatment other than flotation (lack of applicability of other methods is normally indicated by dissemination of valuable mineral in a size too fine for treatment by these methods), the next step is performance of some type of sizing-sorting-assay test.

Sizing-sorting-assay test is directed toward a rapid answer to the question of the sizes at which concentrate and/or tailing can be made in commercial quantities. It comprises, as the name implies, a preliminary separation by size, followed by sorting of the individual sizes on the basis of valuable-mineral content.

Usual procedure is to make first a sizing test of a sample which has been broken to approximately the size at which macroscopic examination indicates that clean mineral or clean tailing can be made, and to assay each such size. This gives a valuable preliminary picture of the material (see cols. 3 to 7, Table 65). Such a test is called a SIZING-ASSAY TEST. Each of the sizes, or groups of adjacent sizes, is next sorted by appropriate means into concentrate, middling, and tailing, and each of these products is weighed and assayed (see cols. 8 to 19, Table 65). Hand picking can be used for separation down to the oversize on a 1-mm. screen, but if concentration criteria permit, sink-float separation will be quicker; if magnetic separation is applicable, it should be used. Panning is useful on the finer sizes, or, if the bulk is large enough, and flotation promising, they may be combined and such a test be made.

Interpretation. Neglecting the middling, or, what amounts to the equivalent, assuming that if it were reground and put back into circuit, the grades of concentrate and tailing would not be affected, the recovery indicated in the test of Table 65 is 96%. It is improbable, however, that middling assaying 14.42% Pb would yield as low a tailing as that yielded by the original ore, assaying 5.27% Pb, especially since in concentrating the original ore a relatively high grade middling was made. If the assumption is made that the concentrate obtained by retreating middling separately would average 65% Pb and the tailing 0.40%, the recovery on middling would be 97.8 %. Such an assumption was

justified in this test on the grounds that microscopic examination of the middling showed that substantially all mineral would be free at 100-m., that the concentrate obtained by floating 14% feed was of somewhat higher grade than that from 5% feed, and that the assays of flotation tailings from the two feeds would be roughly in proportion to the feed assays. Such middling retreatment would add 3.710 tons of concentrate containing 2.4095 tons of lead and 13.386 tons of tailing containing 0.0535 ton of lead. If any doubt exists as to the behavior of the middling on retreatment, it should be ground and treated.

In general the test would not be performed in all of the detail indicated by Table 65; >3-m. would have been hand-picked, 4~8-m. and 10~14-m. would have been hand-jigged or separated by sink-float, 20~100-m. would probably have been tabled (or panned on account of the small bulk), and <100-m. floated.

a Assumed.

From weights: Recovery $= \frac{5.0616}{5.2718} = 96.0$ Ratio of concentration $= \frac{100}{7.488} = 13.3$

From formula: Recovery $= \frac{67.6(5.27-0.227)}{5.27(67.6-0.227)} = 96.0$ Ratio of concentration $= \frac{67.6-0.227}{5.27-0.227} = 13.4$

Preliminary flowsheet. A sizing-sorting-assay test is a basis for a preliminary flowsheet. The test presented in Table 65 would indicate a flowsheet in which the material should be crushed through 3-m., screened on 10-m., the oversize sent to jigs making finished concentrate and tailing, and middling for recrushing; undersize deslimed at 100-m. and the sand tabled to make finished concentrate and, possibly, tailing, with a middling for recrushing; slimes to flotation, making finished concentrate and tailing. On account of the high grade of the primary middling, it would probably be best to grind at least the coarser part lightly to scalp out more concentrate, and even then to grind combined middling separately and float it separately, so that it could be subjected to the relatively slow treatment necessary in making high recovery from rich feed.

Table 65 indicates the relative tonnages that would go to different machines on first pass. The amount that the middling would add would depend on how finely it was ground, whether it was treated separately or thrown back into circuit, and how much recirculation was necessary. These questions can be answered approximately from experience. They cannot be answered definitely without pilot tests on a continuous, as opposed to a batch, basis. This is properly the next step in testing for a flowsheet. It requires a laboratory with pilot-size apparatus, an arrangement sufficiently flexible to permit considerable switching of flow, and apparatus for storage and transport that is specially designed for the small quantities flowing. Otherwise time factors are completely different from those to be expected in a mill, and similitude is lost.

Washability is coal-cleaning jargon to designate amenability of a coal to gravity concentration. A simple washability test on a coal comprises: (*a*) a sizing test on the raw coal; (*b*) sorting each sized product into grades or fractions of different specific gravities from 1.25 or 1.30 to 1.80 or 2.00 by sink-float methods (Art. 20); (*c*) analyzing the grades for ash and sulphur; (*d*) presenting the results of the tests in tabular and in specific graphical forms. The simple washability test is sometimes amplified by so-called SLOTTED-SCREEN TESTS, designed to separate flaky high-ash material from rounded or roughly cubical particles in a given round-hole or square-mesh screen product, either before or after sink-float sorting; and by CRUSHING TESTS, which involve crushing a given sized product and making sizing and sink-float tests, with supplementary analyses of the products,[1] for the purpose of determining the possibilities of enrichment attainable by crushing and concentrating such material. Correct interpretation of the tabular and graphical records of washability tests supplies a basis for reasonably accurate prediction of the behavior of a raw coal or of a sized fraction thereof on gravity-concentration machines. Washability results, carefully performed, constitute a 100% reference point for efficiency calculations.

Similar tests are applicable to ores.

Procedure. SAMPLE for a simple washability test on <3-in. coal should weigh at least 1,000 lb., if analyses on sizes are to be computed from the analyses on the gravity fractions thereof; if independent analyses on the whole size fractions are to be made, the sample weight should be at least 2,000 lb. If crushing tests are to be made additionally, the original sample should weigh at least 4,000 to 5,000 lb., if for no other reason than that such an elaborate program should not be undertaken without an adequate supply of representative material. SIZING should be on a standard screen series corresponding to the practice for the district in which the coal originates. The quantity to be sized should be sufficient to give sized fractions large enough for reliable sink-float separations and for any additional or supplementary tests that may be contemplated. SINK-FLOAT TESTS on the different grades should be made with a sufficient number of sp.-gr. steps to give the desired information. Normally a gravity interval of 0.05, 0.075, or 0.10 in the lower range and 0.15 to 0.20 in the higher ranges is sufficient. For details of testing see Art. 20.

Tabular arrangement of test data is conveniently made as shown in Table 66, which comprises experimental and calculated data from a test by Bird, Gandrud, and Nelson (*3012 RI 17*).

Columns 3 and 5 of Table 66 are experimental figures. Column 4 is a simple percentage equivalent of column 3. Column 6 is the usual cumulation of column 4. Column 7 is the weighted percentage of ash corresponding to the cumulative weight percentages of column 6, *e.g.*, for the 1.30~1.38 gravity fraction of the 1 1/2~3/4-in. size fraction: 0.1 × 4.0 + 5.3 × 5.0 + 61.0 × 9.6 = 612.5, which, divided by 66.4, equals 9.2.

The block described "Raw coal, calculated" is obtained as follows: The figures in column 4 are determined by successive applications of the formula $x = \Sigma ab/\Sigma a$, where a is the weight-per cent. of the size from the last line of each block of column 1 and b is the weight-per cent. of the corresponding gravity fraction from column 4. Thus for the 1.25~1.30 fraction,

$$x = \frac{4.2 \times 11.9 + 5.3 \times 16.9 + \cdots + 34.5 \times 2.0}{11.9 + 16.9 + \cdots + 2.0} = \frac{2{,}725}{100} = 27.2$$

Column 5 is calculated as the weighted average of all of the corresponding gravity fractions of the preceding blocks of the table, *i.e.*, $x = \Sigma abc/\Sigma ab$, wherein a and b are as defined in the preceding sentence, and c is the ash % (col. 5) for the corresponding gravity fraction. Thus for the 1.25~1.30 fraction

$$x = \frac{4.2 \times 11.9 \times 5.2 + 5.3 \times 16.9 \times 5.0 + \cdots + 34.5 \times 2.0 \times 2.9}{4.2 \times 11.9 + 5.3 \times 16.9 + \cdots + 34.5 \times 2.0} = \frac{13{,}379}{2{,}725} = 4.9$$

Columns 6 and 7 are calculated from columns 4 and 5 as previously explained.

The remaining blocks of the table, calculated by the methods used for the raw-coal block, illustrate a method for estimating behavior of any desired composited fraction.

a All ash determinations on moisture-free basis.
b Round-hole screen. Small percentage coarser than 3-in. from crusher.
c Grams.

Interpretation of the data of Table 66 is effected most readily by plotting a part of the figures thereon plus certain other derived figures, as shown in Fig. 142. The curve marked CUMULATIVE graphs directly the relationship between the quantities of columns 6 and 7; that marked SPECIFIC GRAVITY similarly is the direct graph of columns 2 and 6. The ELEMENTARY-ASH curve graphs the ash analysis for a given gravity fraction (col. 5) against the mean of the corresponding and preceding cumulative-weight percentages (col. 6). The scales of abscissae of all three of these curves are chosen so as to produce in all cases substantially the horizontal spreads illustrated. The SPECIFIC-GRAVITY DISTRIBUTION curves are plotted from the specific-gravity curve. Taking the ±0.10 curve as an example, the weight-per cent. of material between gravity 1.3 and 1.5 (= 1.4 ± 0.1) is read from the specific-gravity curve as 81.7 − 27.9 = 53.8, and this value is plotted as ordinate against sp. gr. 1.4, both on the scales of the already existing graph. Other points on the ±0.10 curve are similarly determined; the ±0.15 curve simply takes in a larger range of gravities.

Fig. 142 shows, if entered, say, at 9% cumulative ash, by the intersection of this ordinate with the cumulative curve, that about 79% of the coal may be taken with an average ash content of 9%, and that this coal will float in a solution of 1.44 sp. gr. (abscissa of the intersection of the sp. gr. curve with the horizontal through the intersection of the 9%-cumulative-ash ordinate with the cumulative curve). The abscissa of the intersection of

this same horizontal with the elementary-ash curve, read on the elementary-ash scale, indicates about 22% ash in the most impure fraction of the floated material.

The slope of this elementary-ash curve is an indicator of the ease of washing the coal to a given percentage ash. Steep slope represents relatively small ash and correspondingly small specific-gravity differences, with consequent great difficulty in making clean-cut separation; flat slope represents the reverse physical condition and correspondingly easy separation.

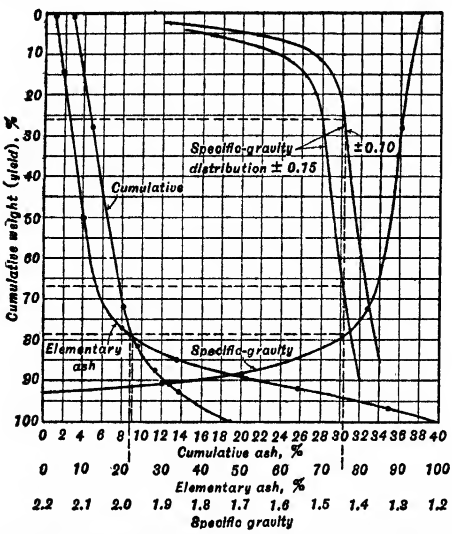

FIG. 142. Washability graph for raw coal (data from Table 66).

The "specific-gravity distribution" curves tell the same story in a slightly different way, in that they read directly the relative quantities of material close to the separating gravity. Bird (*Proc. 3'd Internat'l Conf. on Bituminous Coal*, 1931) correlates the ordinates of these curves with ease of separation as follows: 0 to 7, simple separation; 7 to 10, moderately difficult; 10 to 15, difficult; 15 to 20, very difficult; 20 to 25, exceedingly difficult; over 25, formidable. Applying these criteria to Fig. 142, it is apparent that the elementary ash curve has a constant slope from about 35% ash up, and that this corresponds to 7% or less on the ±0.10 curve; on the other hand, 25% on the ±0.10 curve corresponds to about 22% elementary ash, where the slope of this curve, although definitely steeper than at 35% ash, is not markedly so. Thus the entire gamut of washability from simple to formidable is comprised in the short section of the elementary-ash curve from 22 to 35% and its utility as an indicator is correspondingly poor.

Fig. 142 indicates that an efficient washer (±0.10 curve) will have a simple job separating a coal analyzing about 10.5% ash, making a reject containing material of 37% ash upward, with a theoretical yield of about 85%.

Similar analysis of graphs of the data for individual sizes in Table 66 will give similar information as to theoretical yields and ease of separation of the various-sized products. Practical efficiencies may, of course, be higher, if separation is effected on more or less sized products, but the composite yield can in no case exceed the theoretical yield indicated by Fig. 142.

Significance of inefficiency in washing caused by the attempt to wash to an ash content too low for the coal may be seen by the following analysis based on the curves:

The theoretical yield for 10.5% ash in washed coal is about 85%. Assuming 99% washing efficiency for this easy separation (index 7 on the ±0.10 curve), the actual yield would be 84.15%, or 84.15 tons per 100 tons of raw coal. The theoretical yield for 9.3% ash is about 80%. Assuming 90% efficiency for this difficult separation (index 15 on the ±0.10 curve), the corresponding actual yield would be 72 tons per 100, a drop of 12.15 tons. This lost material, most of which could be recovered as middling in an efficient washery, would analyse 17.7% ash, according to the following calculation:

Units ash in washed coal of first operation, 84.15 tons @ 10.5% =	883.58
Units ash in washed coal of second operation, 72 × 9.3 =	669.60
Units ash in middling (difference) =	213.98
Per cent. ash in middling = 213.98/12.15 =	17.7

Slotted-screen tests are made on sized gravity products with screens having apertures substantially 25, 50, and 75% the width of the aperture of the square-mesh retaining screen and length at least equal thereto, but preferably greater (see Art. 12). Degree of flakiness is thus indicated and, since jig and table separation increase in difficulty with increasing flakiness of the high-ash material, estimates of operating efficiency must be modified accordingly.

Crushing tests are indicated with a coal of the character of that analyzed in Table 66 to determine whether the coarser lower gravity fractions will, when crushed, release sufficient high-gravity material to justify the cost of crushing and the loss through the production of additional fines. Graded crushing with closed-circuiting at each step is usually practiced with a view to reduction of this loss.

22. ORE-TESTING APPARATUS AND PROCEDURES

The machines necessary for a well-equipped laboratory comprise crushers, samplers, weighers, feeders, screens, grinding mills, classifiers, gravity and electrical concentrators, flotation machines, thickeners and filters, and storage and transport equipment.

Crushers. It is not practical to attempt to adapt laboratory crushers to a continuous flowsheet. One crusher, usually of jaw-type (and preferably of Blake-type, from an instructional standpoint, in a school laboratory) should be large enough (7×10-in.) to receive head-size rock, so that run-of-small-mine rock can be reduced to treatment size without excessive labor. Small gyratories are available for secondary service, but a cone crusher small enough is not made (1943). Rolls (12 or 16×10-in.) are best for the fine work required. Performances of laboratory crushers are not safe bases for choice of mill machines. (See Sec. 4.)

Samplers. One machine sampler for dry rock should be available. It is a convenience, if it can take 1 $^1/_2$-in. rock when making a one-eighth cut. It should follow a surge bin designed to discharge completely by a feeder that gives a reasonably constant stream despite a fluctuating head of ore. It is convenient to have the sampler high in the plant, with elevating apparatus to the surge bin capable of receiving from all of the larger crushers.

Most sampling at the finer sizes and/or of small lots is best done by hand-sampling methods (Art. 2).

Weighers. Continuous weighers are not justified. A platform scale weighing in metric and English units to about 1,000 lb. and sensitive to 5 lb., and another weighing to about 300 lb. and sensitive to 0.5 lb. are sufficient for all coarse weighing. For finer work a trip scale weighing in metric and common units to 10 lb. with slide scale graduated to 10 gm. and $^1/_4$ oz., sensitive to 0.5 gm.; pulp balance weighing to 250 gm. and sensitive to 0.1 gm.; and an analytical balance are sufficient (excluding chemical laboratory).

Feeders. Bins should be provided with automatic feeders with variable-speed control and movement-recording apparatus. Belt feeders with ratchet-and-pawl drive and revolution counters on the head shaft are most satisfactory. Self-contained portable vibrating or shaking-tray feeders mounted with small feed hoppers are best for feeding individual machines with dry or moist sands. An inclined trough along which a weighed quantity of dry or moist sand or slime is uniformly spread, and from which a given length (weight) of charge is washed out per minute with a constant stream of water, is the most satisfactory wet feeder for the laboratory. Travel of the feed-water stream may be made automatic by mounting the nozzle on a mechanically driven screw.

Screens that will simulate plant performance in the laboratory are not available as a practical matter. The best approximation for most purposes is made by placing light skirt boards down the length of a small commercial vibrating screen, spacing them to give the desired capacity per sq. ft. of screen surface used; supporting them well above the screen cloth and sealing with light flexible rubber strip; and locating them over that part of the cloth that has nearest the average vibration. The screen is preferably placed to receive from the sampler surge bin, so that some idea can be gained of the effect of closing circuit on the rolls. With such an arrangement it is possible to start a continuous operation with screen-sized feed, although the rolls in such a laboratory circuit will usually be woefully underloaded.

Grinding mills of the tumbling type are available in any desired size. It is probable that the best arrangement from the standpoint of a continuous operation is to choose a mill that will operate normally at a capacity equal to that of the concentrating and/or other equipment that is to follow it, and to design for removal or addition of shell (bolted-in sections, with a head-end drive and a sliding base for the discharge end) to accommodate for other capacities. The same shell will take any grinding medium desired. The installation may well be made to permit of closed circuits for both wet and dry grinding, with either screens or classifiers as the closing apparatus. Since tumbling mills will do just about the same amount of grinding per unit of energy input irrespective of size, if the limiting size of feed is adjusted to the diameter, and circuit conditions are comparable, considerable information useful in flowsheet design is obtainable from laboratory grinding tests. On the other hand, the operating difficulties in the way of balancing a closed laboratory grinding circuit with small concentrating or cyaniding apparatus are formidable; the job cannot be done dependably short of many hours or even days of operation, and overnight shutdowns are, in most cases, fatal. The larger the grinding mill and subsequent apparatus the easier the circuit will be to operate. The grinding machine should be so driven that reasonably accurate measurement of power consumption can be made.

Classifiers. Laboratory classifiers comprise both models of mill-scale apparatus and batch units devised for very small test lots and for investigation of fundamentals. The forms of the latter are legion. Descriptions of some of the better-known types follow.

In general, however, experimenters make up this kind of equipment to satisfy the demands of particular experiments.

Classifier tests give information, not yielded by screen tests, as to the distribution of material to be expected in a gravity-concentration plant; and, in conjunction with screen tests, form a basis for prediction of the results to be expected from gravity-concentration treatment. Testing classifiers are also used to prepare material for concentration tests on shaking tables and the like. Elutriation tests (Art. 13) are classifier tests applied to sizing fine material, but these same tests, subjected to different interpretation, give useful information regarding gravity concentration.

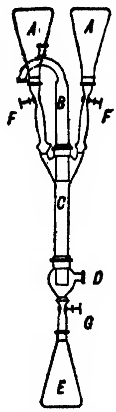

FIG. 143. Munroe tube classifier.

Beaker classification involves the same manipulation, in so far as separation into different grades is concerned, as the decantation method of sizing by elutriation. When applied to coarse material (0.5-mm. to, say, 2.5-mm.) the time required for settlement is so short that there is much overlapping of the grades and results are very different from those attainable in a rising-current classifier.

Sorting tubes are made in glass for both free-settling and hindered-settling classification (Sec. 8, Art. 1).

Free-settling tube (designed by H. S. Munroe and manufactured by Eimer & Amend and by Emil Greiner, N. Y.) is shown in Fig. 143. The essential parts are sorting column *C* with feed inlets *F*, vortex fitting *D*, overflow tube *B*, and feed and spigot flasks *A* and *E* respectively. Joints between flasks and apparatus are made with rubber tubing. The ends entering the flasks are expanded by means of brass thimbles of suitable diameter slipped inside the tubing. Joints between *B–C* and *C–D* are made tight by rubber tubing slipped over the lower ends of *B* and *C* respectively. The annular space between the lower end of *B* and constricted portion of *C* should be about 1/8 in. wide. The lower end of *C* should project about 1/2 in. below the bottom of the water inlet in *D*. When set up, the tubes *B* and *C* should be clamped rigidly in vertical position in a ringstand which carries also two large rings near the top in which flasks *A* may hang. Flask *E* should rest on the base of the stand. There should be no kinks in the rubber tubes connecting the flasks. Tubes are made in several sizes, ranging from about 1- to 3-in. diameter of sorting column *C*. The actual average internal diameter of *C* is obtained by measuring the water drawn from between spaced marks and applying equation $Q = Av$ (see Sec. 20, Art. 2). The quantity of water necessary to overflow in a given time in order to produce any required average rising velocity in *C* may then be calculated from the same equation and the desired current set by bringing the overflow to this figure.

Procedure. A weighed sample of ore is divided about equally between the two flasks *A*. Enough water is added to moisten the ore thoroughly, with shaking; the bottles are then filled with water, and put into position for feeding, the cocks *F* being closed. The rubber tubes must be full of water both above and below *F*, because an air bubble prevents proper discharge of ore. Having adjusted the flow of water up the column to the desired velocity, cocks *F* are slightly opened to allow ore to drop slowly. Light material will be carried over, while the heavier will fall through the rising current and into flask *E*. When all ore is out of the upper flasks, a few minutes are allowed for the sorting column to clear partially, the current is then shut off and a little more time allowed for matter still in suspension to settle. Cock *G* is then closed, flask *E* removed, and its contents transferred to feed flasks *A*. This last operation may be simplified by having at hand an extra flask *E* filled with water; when about half the ore has fallen into the first flask, it may be replaced by the second flask, after closing *G* temporarily. Two flasks *E* may then be put into the position first occupied by flasks *A*. Current is now adjusted for the next faster velocity desired, and the operations repeated. While working with velocities up to, say, 20 mm. per sec., it is well to catch the entire overflow, water and solids, in pails which may be set aside for a sufficient length of time to permit solids to settle perfectly; with the higher velocities, overflow may be led to pans in which solids will settle while water overflows. Solid matter carried over at each velocity is caught separately, dried, and weighed.

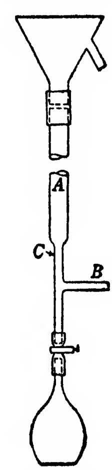

FIG. 144. Hindered-settling tube.

Hindered-settling tube (Fig. 144) consists of a glass tube *A* about 1-in. diameter and 30 in. long, drawn down at the lower end to smaller diameter, and provided with a side tube *B* for water inlet. The ratio of the diameter of section *C* to that of section *A* for all-around work on feeds ranging from, say, 2-mm. maximum to 0.5-mm. maximum should be 1 : 2, but a ratio of 1 : 1.5 is better for the coarse separations and one of 1 : 3 or 4 for fine sizes, and a series of tubes is best for close work. The length of section *C* should be 3 to 4 in. Inlet *B* and the spigot should be about 1/4-in. internal diameter. A galvanized-iron or sheet-copper funnel with side tube about 3/4-in. diameter should be provided for feeding and collecting overflow, and a number of small-necked flasks for collecting spigot products. The joint between tube and flask is a rubber tube controlled by a stopcock.

Final settlement of any particle is determined by its ability to pass the constricted section *C*, free-settling against a given current. Hence this is the important diameter, and currents are set for section *C* by the methods described under *Free-settling tube* above.

Operation starts by filling the entire system with water, then setting the minimum current (about 5 mm. per sec.) and feeding material slowly into the funnel. The feed should be wet to prevent skin flotation and the best results will be obtained if the slimes are slowly decanted into the funnel several times before any of the sands are poured in, taking care that the rate of feeding slimy water is insufficient to make the rising current at the overflow level equal to or greater than that in section *C*. Collect the slime in a pail and set aside. The water in the flask should be slime free; if not, refeed the spigot product. Collect the spigot product. Set the current at the maximum rate, refeed the first spigot product, run until only an occasional grain falls through section *C*, then close the stopcock, collect the spigot product, and replace the flask, full of water; slack off the current gradually until the next lower current is reached, open the stopcock, feed back any sand that overflowed in the preceding operation, and run as before until settling substantially ceases. Repeat with decreasing current velocities until the 5-mm. velocity is again reached. It is better to run at this current a second time, adding the overflow and material remaining in the teeter-chamber *A* to the first overflow. Dry and weigh the products.

Constriction-plate hindered-settling classifier (*RI 3328*) consists of a pyrex tube, 6(diam.)×30-in., surmounting a flanged cone with a constriction plate between cylinder and cone. The plate is brass, drilled with 3/64-in. holes at 3/8-in. centers on a 60° diagonal pattern. The cone is provided with a water-entrance tube. Overflow from the tube is caught and discharge by a slanting peripheral launder mounted at the top of the settling column. The classifier has a capacity of approximately 25 lb. of <10-m. material.

Operation of the classifier is as follows: Water is fed into the glass tube until a depth of 6 to 10 in. is obtained, and very slight flow is continued while the ore charge is introduced. After introduction of the charge, flow is controlled so as to produce overflow of slimes, which are caught in a tub. Thereafter water flow within the tube is increased until the entire column of ore is in teeter and continued until the grains have had time to adjust themselves and find their proper static environment relative to other grains; stirring with a long steel rod aids in attaining this condition, by freeing trapped grains. The water is then entirely cut off until a compacted bed is formed. It may then be turned on again to such extent as will permit some overflow but will not loosen the compacted bed. The column is divided into spigots by visual inspection and each spigot is siphoned off in succession from the top downward. Three spigot products are usually made, though as many as five may be produced.

This classifier is a development of the hydraulic sizer described by Fahrenwald (*A TP 275*) which has a capacity of about 1,000 gm. of solid.

Multispigot classifiers. Miniatures of mill-type classifiers (Sec. 8) are used. The most satisfactory miniatures are those of the tank type, either hindered-settling or free-settling. Fig. 145 shows a useful size, which has a capacity of about 1 kg. per min.

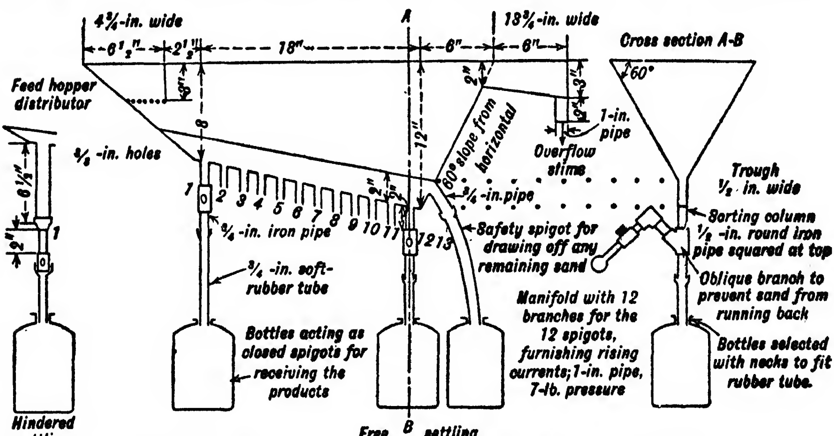

Fig. 145. Laboratory tank-type classifier (*after Richards, 91 J 415*).

Laboratory classifiers are much more conveniently operated with closed spigot, when possible, as it is then unnecessary to supply and dispose of large quantities of spigot water.

Interpretation of classifier tests. The weights of the products tell the tonnages of different grades for which concentrating machines must be provided. Assays of the combined products do not yield much information concerning probable mill performances, on account of the middling present; actual concentration tests should be made. Sizing the products on a series of screens will approximate the work of shaking tables, the finest sizes representing concentrate, the coarsest the tailing, and the intermediate, middling. If the sized products are laid out on a ruled board in such a way that the abscissa of any grade is the number of the classifier spigot from which it came and its ordinate the screen

size, an excellent picture of the work of the classifier is obtained. The best classification is represented by maximum spread on this board between the heaps of pure heavy mineral and pure gangue. The smaller the middling heaps, the heavier the loads that can be put on the following shaking tables; and, of course, the size of the middling heaps indicates the tonnage that must be reground.

Settling ratio is the ratio of the average diameter of light-mineral grains to that of the heavy-mineral grains in a classified product. It may be calculated from the layout described in the preceding paragraph by sorting out the middling grains in the various heaps, assaying the residues for heavy mineral, and then calculating average sizes of the two kinds of grains in each spigot product. The larger the settling ratio the easier the work of the concentrator treating the product and the better the work of the classifier. *Richards* has determined the average free-settling ratio of quartz and galena as about 4 and the hindered-settling ratio slightly less than 7. These figures were obtained by careful laboratory work with artificial mixtures of the two minerals and making a large number of successive spigot products with small current differences. Excellent mill work will show not more than 2.5 and 4 respectively for these same minerals, on account of the smaller number of spigots, the interference by middling grains, and overloading of the classifier.

Mechanical-classifier tests can be made properly only in machines of the type concerning which information is sought, and, since so many other factors than simple settlement in water are involved, *e.g.*, agitation, time of draining sand, slope of draining surface, depth of pool, and the like (see Sec. 8), it is almost essential that the testing machine be a replica of the full-size machine, in longitudinal section at least, and even then it is doubtful whether the small apparatus will even approximate the work of the large machine.

Drag and spiral types are available in manufactured form; the reciprocating-rake type is not. An attempted substitute therefor is shown in Fig. 146. It is essentially an inclined flight conveyor modified to drag intermittently. Drag chains (*1*) carrying transverse flights (*2*) run over the lower sprocket

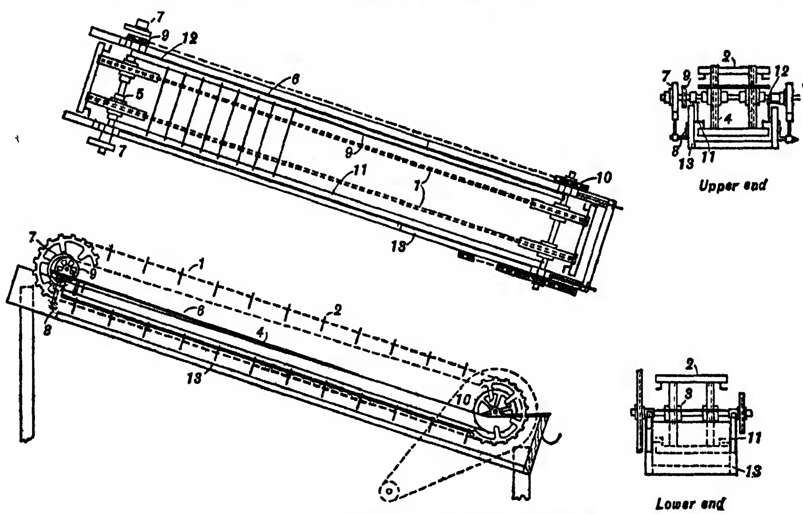

FIG. 146. Intermittent-drag mechanical classifier.

wheels (*3*) to which power is applied by drive sprocket (*10*), and over upper sprocket wheels (*4*) which idle between collars (*5*) on a shaft mounted in eccentrics (*7*). The shaft bearings are mounted on long hinged arms (*8*) so that the shaft may be raised or lowered relative to the inclined trough (*13*) in which the flights operate. The distance between head and tail sprockets is unaltered by such variation. The eccentrics are attached to the ends of the driven shaft and are pivoted in the supporting brackets (*8*) located below the shaft. The flights are provided with arms that ride on the flight-guide bars (*11*), which are hinged at their lower ends and attached to the upper shaft by means of hangers (*12*). This mounting of the upper shaft permits the eccentrics to move back and forth while the shaft rises and falls as it rotates. This latter motion is imparted to the flights by means of the guide bars. The entry point of the feed is a short distance above the drive shaft. In operation sand is dragged uphill for a short distance by the flights, which gradually rise and so spread the sand heap. After a short interval the second or third succeeding flight descends and repeats the cycle.

Thickening. For methods of testing see Sec. 15, Art. 6.

Bond (*141 #1 J 54*) describes an integrating scale for the calculation of settling area from a settling test. Graduate a celluloid scale, 1×16-in., into 6 @ 2 2/3-in. divisions, and subdivide each major division into tenths. By measurement of the distance between cylinder graduations determine the value of 2 2/3 in. in cubic centimeters. This value, designated by J, is ordinarily about 195 cc. This number in grams is the dry weight of ore to be taken with this graduate. $J/G_s = V_s$, where G_s = specific gravity of dry ore, and V_s = cc. occupied by dry solids. Place the zero point of the celluloid scale at the level V_0 on the graduate scale (ordinarily about 75 cc.). The celluloid-scale division now will read dilutions at any stage of settling, and

$$A = (F - F_f)/10X$$

where X = celluloid-scale divisions settled per min., and F and F_f are successive dilutions and final dilution respectively.

Filtration. The usual test apparatus is a small filtering surface reproducing essentially the type of surface to be investigated. The Oliver Filter Co. uses a filter-leaf frame of the form shown in Fig. 147, item Y, made of Bakelite, cast in one piece. A stainless-steel

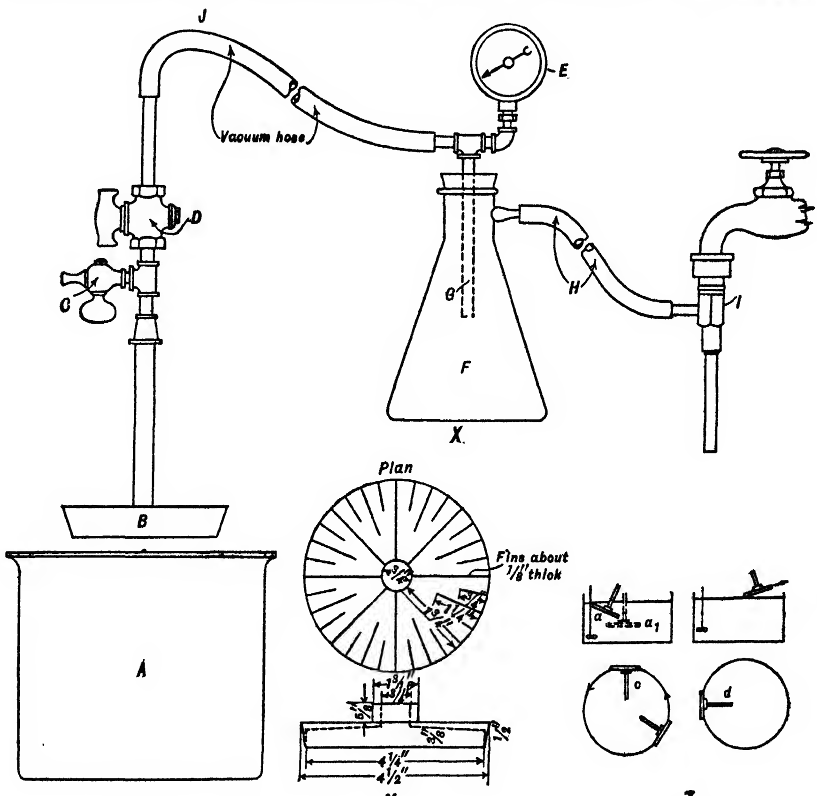

FIG. 147. Apparatus for filtration tests.

band, with inside dimensions about 1/32 in. larger than the frame, is provided. To prepare the test leaf, a piece of filter cloth is cut large enough to cover the frame and turn down over the edges; it is placed over the frame, and the band is forced down so that the cloth makes a tight fit at the edges. The filter leaf is then connected into the typical test-leaf hookup shown in item X, comprising a container A for the slurry, with means for maintaining suspension; the test leaf B; flexible connecting piping containing a vent cock C and shutoff cock D, and attached to a vacuum gage E or a mercury manometer or other pressure-measuring device; a vacuum receiver F, which is preferably transparent and large enough to receive a graduate under the filtrate pipe G, so that filtrate volume can be read directly during operation; and connection H to a source of vacuum, which is conveniently a water aspirator I, as indicated.

Test procedure is designed to simulate the cycle of a particular type of filter. For example, the cycle of a drum-type filter (Sec. 16, Art. 3) may be broken down into (1) a cake-forming stage, during which the cloth is submerged in the pulp and is under vacuum; (2) a cake-drying stage during which cloth is out of contact with the pulp but still under the action of the vacuum; (3) a cake-discharge stage begins when the vacuum is shut off and ends with resubmergence.

In testing to parallel plant performance, the test pulp should have the same temperature, pH, and state of dispersion as the pulp to be supplied to the filter in the mill. The test should be performed at such pressure as will be available at the mill; elevation of mill above sea level and vacuum equipment to be used are the controlling factors.

Preliminary run is made to determine the time required to form a dischargeable cake. With stopcocks C and D closed, introduce test leaf as at a, item Z; when immersion is complete, turn on vacuum, which will have been built up to the desired level in F, and note time; move leaf slowly through the well-stirred pulp, following a circular path; note vacuum; finally, bring leaf out of pulp as shown; shut off vacuum, and note time. The time elapsed is the cake-forming time. The cake should be dried and its thickness determined by placing several pieces on top of each other, measuring total height and computing average thickness. The time required to produce minimum thickness of cake that discharges cleanly is the desired cake-forming time, since maximum filter capacity is obtained with this minimum cake thickness or one only slightly larger.

Test for filter capacity is made by repeating the procedure of the preliminary test, using the cake-forming time determined therein, and holding the cake in position a_1, if necessary to prolong the period. When the leaf is removed from the pulp it should be brought up slowly through a circular arc with center at J until past the horizontal position to the position shown in c, item Z. Time for this should range from once to twice cake-forming time. Shut off the vacuum and note the time. Normally cake may now be dislodged by blowing through the vent; stubborn cake must be dislodged by means of a spatula. Place the cake in a tared dish, weigh, dry, and weigh. Note and record total filtrate. From dry weight of cake and filter area, capacity expressed as tons per sq. ft. of filter area per revolution may be calculated. Time per revolution depends on cake-forming time, cake-drying time, cake-washing time if washing is practiced, and discharge time. Washing time depends upon rate and type of washing, which depend in turn upon the character of the cake and the amount of cleaning required. It may be approximated by spraying the cake while moving from c to d, item Z. Discharge time is not measured; it is usually assumed to be one-half of forming time. Relation of cycle time to forming time, wash plus drying time, and drum submergence is given in Table 67.

Calculation. When cycle time is known, capacity figures on an hourly or daily basis can be calculated.

Example. If the wash plus drying time equals forming time, and a 0.1-sq. ft. filter leaf made 0.2 lb. of cake (dry weight) in 1/3 min. submergence time, this is equivalent to 2 lb. per sq. ft. per rev. or 288 lb. per sq. ft. per 24 hr. If 10,000 lb. of solid is to be filtered per 24 hr., it will require 34.7 sq. ft. The corresponding size of commercial filter can be chosen from this figure. It is good practice to reduce filter capacities determined by laboratory testing by multiplication by a factor which makes allowance for fluctuations of plant conditions, blinding of cover, etc. This factor varies from about 0.8 to 0.65. Pulps containing free lime take the lowest factor since carbonate formation on the surface of the cloth decreases its permeability.

Laboratory-size filters of the drum and leaf types, suitable for more extensive testing, may be purchased from the manufacturers.

Table 67. Relation between times in a revolving-filter cycle

Submergence, % of diameter	40	25	20	16	12
Submergence, % of circumference	43.5	33.5	29.5	26.5	23.0
Maximum cake-forming arc, deg	135.0	100.0	93.0	82.0	68.0
Washing and drying arc, deg	167.0	214.0	219.0	238.0	249.0
Discharge arc, deg	58.0	46.0	48.0	40.0	43.0
Cycle time *a*	3*F*	4*F*	4*F*	4 1/2*F*	5 1/2*F*
Wash and drying time	*F*	2*F*	2 1/2*F*	3*F*	3 1/2*F*

a F = cake-forming time.

Concentration Tests

Hand-picking often affords valuable information, even when not considered a practicable method of treating a given ore under existing conditions. It may be applied to ore as fine as pea-size; and, in the investigation of screened products, may be carried down to 1.0- or even 0.5-mm. with the aid of a hand glass or a low-power binocular microscope. For satisfactory hand-picking, ore should be sized between rather close limits, and should be clean; washing brings out the distinctive color or luster of some minerals.

Practicability of hand-picking on a commercial scale may be tested by attempting to make the following products, or as many of them as practicable: (*a*) Rich minerals, fit for market or for metallurgical treatment. These will include not only such minerals as galena, blende, chalcopyrite, etc., nearly or quite pure, but also rich mineral which possibly can be treated better by some metallurgical process than by mechanical means, for example copper carbonates, silver chloride, finely disseminated silver ore, etc. (*b*) Rich ore, with coarse disseminated mineral, for coarse crushing and jigging. (*c*) Fine-disseminated ore, usually poor, in which the useful mineral occurs in such small particles that

exceedingly fine crushing will be necessary to liberate it. (*d*) Barren waste, or material that does not seem to be mineralized. Several classes may sometimes be made of this, according to gangue minerals or rocks in the ore, or when a difference of color, texture, or other characteristic indicates a possible difference in richness. Assays of these different classes of barren or seemingly barren material will show which may be thrown away, and which should be included with the ore for milling. Finally, inspection of the different products may show that some classes are present in small quantity only, and that perhaps several sorts may be combined without disadvantage.

Economy of hand-picking may be investigated by means of the formulas in Art. 24.

Jigging. When a preliminary examination of the ore indicates the feasibility of jigging (or tabling) as a mode of concentration, it is good practice to run sink-float tests (see Art. 20) on sized samples. The information thus obtained will establish grades and recoveries to be expected. Generally speaking, a specific gravity difference between mineral and gangue giving a concentration criterion of 1.75 (Sec. 11, Art. 1) is sufficient for successful application of gravity methods. However, if marked differences of shape exist, the specific gravity difference must be greater. For example, spodumene (sp. gr. 3.15) tends to go with quartz (2.65) and feldspar (2.6), because it breaks into acicular particles whereas the others break more or less equiaxed. Micaceous minerals usually produce platy particles on fracture; these also tend to go with lighter minerals.

Hand jigging, for testing ore ranging in size from 10- to 2-mm., requires a tub of water and a few small screens of differing mesh. Before jigging, the ore should be sized fairly closely.

Procedure. Put about 2-in. depth of sized ore into a sieve having a mesh fine enough to retain it, and jig for several minutes under the surface of the water, with a long, slow stroke for the coarser sizes, and a shorter and quicker stroke for finer sizes. A quick downstroke combined with a slower upstroke is best. Care should be taken to keep the sieve level and to avoid any horizontal or overturning movement of the mass of ore. When the tailing appears clean, scrape off the upper layer and replace it with an equal amount of ore, and resume jigging. Middling and concentrate should be allowed to accumulate unless the layers become too thick. The main object of this preliminary jigging is to produce tailing as poor as possible. When the whole sample has been treated, the accumulated concentrate is cleaned by careful jigging, aided by hand-picking, if necessary. Skimmings from the cleaning operation should be added to the middling and the whole rejigged and reduced to the smallest possible bulk by combining part with the concentrate and part with the tailing. Assays and microscopic examination of the products will indicate the maximum size at which jigging can profitably begin.

A rather more elaborate hand jig, described by *Richards*, consists of a square frame about $12 \times 12 \times 6$-in., made of heavy galvanized sheet (10- to 14-gage) turned over $1/8 \times 1/4$-in. strap top and bottom for stiffness. Slats of the same strap to support the screen should be placed 2 or 3 in. above the bottom of the frame and the screen wired thereto. It is desirable to solder the joint between screen and sides, but this makes it difficult to change screens, if desired. Otherwise some leak at the edges must be tolerated. In operation the screen is hung from a helical spring at the desired height above the tub in which jigging is to be done and is then plunged and lifted in the usual manner.

Machine jigging. Experimental jigs for testing purposes, operated by hand or power, are made by manufacturers of commercial jigs; they are useful equipment for testing laboratories, but their results are no more illuminating than those obtained by hand jigging, except that they are superior for hutch making. All small-scale continuous jigs are subject to the disadvantage that the ratio of dead space along the sides to total sieve area is relatively large and that an undue amount of heavy grains travels along these dead sides into subsequent compartments or even into the tailing.

Pan; gold pan; miner's pan are different names for the same device. (See Sec. 11, Art. 14.) The pan has three principal uses, *viz.*, (1) to assay gold-bearing gravels in prospecting, and less frequently, to make a rough assay of crushed vein material for gold; (2) to work gold-bearing gravel on a small scale; (3) to make gravity-concentration tests on heavy-metal ores. The procedure differs according to the material being panned.

Method of gold panning is to take a pan load, submerge it, then work the material over carefully with the hands, rejecting large boulders that are free of adhering fines and clayey material, until all of the coarse material is removed and all clayey or cemented material is disintegrated. Next, with the pan submerged or with the material in the pan submerged, holding the bottom substantially horizontal, subject the pan to a rotary motion of sufficient intensity to produce suspension of the solids. The heavy particles, being more resistant to suspension, work toward the bottom and leave the surface metal-free. Now, with the pan above the water surface, tilt it slightly away from the operator and at the same time rock it from side to side. The resulting action of the water tends to wash solid matter to the lower edge, and the amount of tilt and speed of rocking should be such that only the surface layers of particles are washed down into a TOE at the lower rim. The toe is next washed off by alternately dipping and raising it through the water surface, or is pushed off with the thumb. These three operations are repeated in order until the amount of material remaining in the pan is small and consists of heavy minerals and some fine light sand. Further separation can sometimes be made by moving the pan in such a way that a small amount of water therein will course around the trough formed by the intersection of side and bottom. Such treatment strings out the material with the lightest sand ahead and the heavy material bringing up the rear, and it is often possible, by careful manipulation, thus to work out a further quantity of light sand. This treatment will usually, also, bring any gold to

light at the tail of the fan of material. Final separation of gold from the heavy minerals is made by amalgamation or by drying, separating magnetite with a magnet and the balance of the waste by blowing (Sec. 11, Art. 34).

Testing an ore differs from the above procedure in that (1) the ore must first be ground to a size that will free a goodly part of the valuable mineral, (2) the weight of the sample taken can be and should be determined, (3) stratification requires more careful and prolonged swirling, and (4) the thickness of the surface layer removed in each cycle must be thinner. The operation should be conducted over a tub in which the first tailing is collected for repanning. Concentrate will always contain considerable gangue and the tailing some valuable mineral. In the hands of an experienced operator the recovery will be about the same as is possible in mill work, but mill concentrate, especially the coarser sizes, will assay higher.

An experienced panner, working steadily, can treat about 100 pans of uncemented gold gravel per 10-hr. day, and proportionately less according to the degree of cementation. The same man cannot run down more than one-third as many samples of galena-quartz ore and even less of ores in which the difference in specific gravities of heavy and light minerals is smaller.

Haultain Superpanner (*40 CIMM 229*), Fig. 148, consists of a flat V-shaped pan, 10 in. wide, about 1 in. deep at the head-motion end, and about 2 in. deep at the other end, to the upper surface of which linoleum is conformed in such a way as to do away with edges and corners. The pan is so shaken by the combined actions of the longitudinal and transverse rocking motions that a point of the pan describes an egg-shaped path (with the pointed end oriented toward the head motion). The pan is carried by a longitudinal wooden member A to which are attached two sheet-metal cross-members B and C; the assembly resting on the upper ends of 4 piano-wire rods attached at points B_1, B_2, C_1, C_2, which pass through the sheet-metal base D. Longitudinal motion is imparted by a single-arm cam E rotated by a variable-speed electric or air motor F. Length of longitudinal stroke is changed by rotating an eccentric mounted on the motor shaft next to the cam. Member A is held up against the cam by spring G acting through lever H and controlled by hand wheel I. Sidewise motion is produced by moving notched flats J and K, loosely held at one end by bolts and attached at the other end to cranks operated by shaft L, which is driven by a variable speed motor M. The motion is transmitted at the head end through a wire S directly attached to A, and at the tail end by wire T attached to one end of lever N and by wire U attached to the other end of N and to A. Springs O and P, attached to A, may be varied in tension by varying the lengths of wires Q and R; they act as restituters of the sidewise motion. The pan is attached to A in the position shown by the dotted rectangle in Fig. 148, and is provided with two tubes (one at the head and the other at the foot of the pan) adjustable as to position above and across the pan. The tube at the head-motion end is connected to the water supply; the tube at the foot of the pan to a demijohn under reduced pressure.

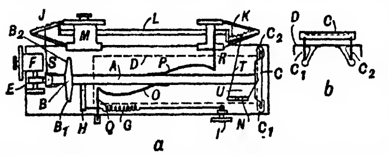

FIG. 148. Diagrammatic sketch of Haultain Superpanner.

Adjustments are slope, speed, and amplitude of longitudinal motion, intensity of end bump, speed of side stroke, amplitude thereof at head and foot of the pan, amount of wash water, and depth of pool at the feed end. Usually only three of these adjustments are varied—slope and the speeds of the end and side motions. Depth of the pool varies during a run with removal of material. De Rycker and Rey (*141 #12 J 46*) eliminated the bumping post and substituted a special cam designed to give quick-return motion, keeping contact with the cam by means of springs. This change eliminates stroke setting. Direct tailing overflow was provided with a raised lip, making a small pool to give a slight hold-back; the weir was made narrow.

Elements of action are: (1) End-bump to move material forward, with the pan shape acting to confine solid into an ever-narrowing pocket, (2) side motion to maintain fluidity of mass and permit stratification, (3) washing to skim the surface of the advancing material, the tilt of the pan and the side motion aiding.

Applicability. The Superpanner makes separations of materials with specific gravities very close together and will separate minute amounts of heavy mineral, if present. Thus 5- to 15-μ gold was separated from a tailing where a prolonged microscopic search failed to find it. The range of sizes that can be treated is from 65-m. down to 14-μ; results through this range are quantitative; for smaller sizes qualitative information is afforded. Use of heavy liquids, *e.g.*, acetylene bromide, improves performance. The chief utility of the Superpanner in laboratory testing is in production of clean concentrate and tailing. These products may be used to determine mode of occurrence and association of particular minerals either by assay or microscopic examination. Its ability to separate minute amounts of heavy mineral, and to separate mineral pairs such as gold from gold tellurides, or chalcopyrite from sphalerite, makes it a powerful tool.

Vanning is somewhat similar to panning but not applicable to as coarse material (0.5-mm. max.) and limited to much smaller quantities, *e.g.*, about 50 gm. Vanning plaque is made of enameled iron in the shape of a spherical segment, about 12-in. diameter and 3/4 in. deep at the center. The Cornish vanning shovel is essentially a plaque mounted on a handle about 24 in. long. A batea or a large watch glass may be used as a substitute for a plaque.

Procedure. The sample, if dry, is first wet down carefully, taking pains to prevent skin flotation. The wet pulp is then swirled vigorously to get the slime in suspension, next more slowly to let all granular material settle, after which slime is decanted. This operation is repeated until all slime is removed. Thereafter the elements of a vanning operation are threefold, *viz.*, (1) stratification as in panning, (2) throwing the lower stratum (heavy concentrate) to one edge of the plaque while the upper stratum remains nearer the center, and (3) washing the upper stratum to and over the side of the plaque away from the head of concentrate. Stratification is effected by simple swirling of the pulp by a horizontal rotary motion of the plaque. In order to throw up the head of concentrate the plaque, held on opposite edges in the two hands, is moved as in swirling with one hand while the other describes, at each revolution, a small vertical circle, say, 1 in. in diameter, in a clockwise direction, moving downward more rapidly than upward. The swirling motion keeps the upper stratum in suspension while the lower stratum hugs the surface; hence as the plaque moves away from the operator the heavy material moves with it, but it moves from under the gangue in suspension. The rapid downstroke drops the plaque from under the heavy mineral and when the latter again reaches the plaque surface it rests at a point farther away from the operator than before. The head of concentrate is, in this wise, made to travel up onto the edge of the plaque away from the operator while the lighter sands remain nearer the center. Horizontal separation is continued by imparting a gentle swirl that moves the water only, and giving the plaque a smart shake at the time that the swirling water is traveling away from the head of concentrate. In this way the sand is washed down-slope toward the operator by film-sizing action (Sec. 11, Art. 30). Some operators manipulate the second phase of the separation so as to draw the head toward them and wash tailing off the far side. Others throw up the head by simple swirling with one hand and jarring the side of the plaque at each revolution against the heel of the other hand. In the latter case the mechanics of the horizontal separation is different, but the result is the same. This method is easier to learn than the other, but is very tiring, if much vanning is to be done. With a vanning shovel the head is thrown up by a slight side fillip on the backward stroke of the swirl.

Principal uses of the vanning plaque are in examination of finely ground mill products, and in assaying, particularly in CORNWALL to assay tin ore. Vanning has the advantage over a chemical assay that it gives some idea of the amount of middling grains and of the size of the free-mineral grains. It has been largely superseded in Cornwall tin assaying by chemical methods, but for many years it was the principal, if not the only, method of assaying used in that district. It had, of course, the apparent advantage that it indicated only recoverable tin, *i.e.*, free cassiterite of a size that could be won by gravity concentration, and this was all that most millmen were interested in, but careful experiment show that skilful operators reported discrepant results on the same sample and that none, of course, checked the chemical assay.

Shaking tables of laboratory size, with interchangeable decks for coarse and fine feeds, may be purchased. Results obtained with small tables are substantially the same as those obtained with full-sized machines.

Laboratory tables should be set up with variable-speed drive and with provision for making more than the usual number of splits of the discharge. Much information can

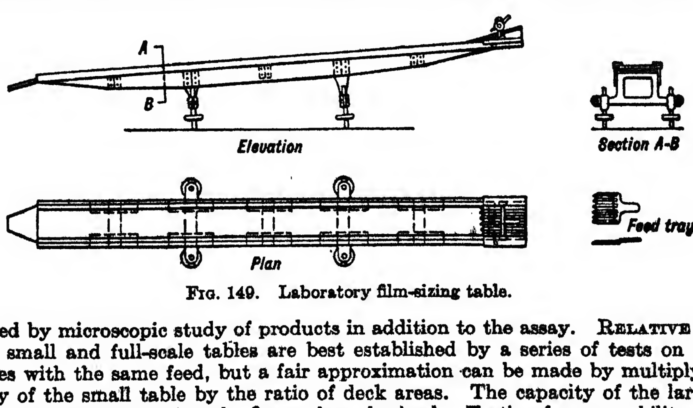

FIG. 149. Laboratory film-sizing table.

be gained by microscopic study of products in addition to the assay. RELATIVE CAPACITIES of small and full-scale tables are best established by a series of tests on the two machines with the same feed, but a fair approximation can be made by multiplying the capacity of the small table by the ratio of deck areas. The capacity of the large table will usually exceed somewhat the figure thus obtained. Testing for amenability to table separation is made only when the decision, based on specific gravity differences or sink-float tests, is close.

Agglomerate tabling; see Sec. 12, Art. 30.

Vanners and buddles. Performances can be approximated by use of a shallow trough, 3 or 4 ft. long and 8 to 12 in. wide, with a bottom of planed board, ground glass, linoleum, or the like, resting on adjustable supports.

A more elaborate form (designed by H. S. Munroe and made by Eimer & Amend, N. Y., Fig. 149) consists of a strong metal frame about 3-in.×3 or 4-ft. in which flat plates of pine, maple, slate, glass or other material may be interchangeably secured. Inclination is adjusted by leveling screws, and amount of water by a dial cock to effect the desired separation. A portion of wet ore is gradually pushed under water jets at the head of table, care being taken not to feed too fast. After 2 or 3 min. the feed is interrupted and material on the table is washed 2 or 3 min. until most of the tailing has run off. The tailing pan is then removed, and middling and concentrate are successively washed off with a jet of water, into separate pans. By making at first a large proportion of middling, clean concentrate and low-grade tailing may be secured. Next wash the middling by itself, varying the amount of water and inclination of table to suit.

Performance of the laboratory table gives no direct information as to the capacity of mill-size machines, except in so far as it shows separation to be difficult or the reverse. See also *27 A 76*.

Sink-float tests are made for plant-control checks, for sorting in sizing-sorting-assay tests (Art. 21), for so-called washability tests, *i.e.*, tests for amenability to standard gravity concentration procedures, and to test ores for amenability to the sink-float process itself. Heavy liquids are ordinarily used for the first three purposes (Art. 20); the process test is made with typical liquid-solid suspensions (Sec. 11, Art. 28). Table 68 gives properties of various proved suspensions.

Table 68. Properties of suspension (*after DeVaney and Shelton, RI 3469R*)

Material	Hardness mohs	Sp. gr.	Maximum sp. gr.	Resistance to corrosion	Method of cleaning
Sand............	7	2.65	1.8	High	....
Clay............	2 to 2.5	2.0 to 2.6	circa 1.6	High	....
Magnetite.......	6	5.1	2.55	High	Mag. sep.
Galena..........	2.5 to 2.75	7.5	4.3	Oxidizes	Tabling

Lead............	1.5	11.3	6.2	Oxidizes *d*	....

a Rockwell. *c* Oxidation reduced by addition of lime.
b 15% SiO_2. *d* Addition of $S^{=}$ helps to prevent oxidation.

Suspensoid process. Testing an ore for amenability involves both determination of the separation that can be made and finding the suspensoid that will perform best. The first test is easy; the second is probably beyond the scope of laboratory procedure in the present state of knowledge of the process.

Test for separation consists in making up a suitable suspensoid, placing it in a separating tank; feeding to it sized, washed ore in an amount that will produce a float 3 or 4 grains deep; stirring sufficiently to permit separation, allowing a few minutes thereafter for stratification, then skimming float, screening out both float and sink from medium, washing each thoroughly with water on a screen, drying, and assaying. Maximum size of feed depends on dissemination of valuable ingredient in the crude, and is probably most quickly determined by a preliminary sizing-sorting-assay test; the process itself imposes no practical limit. Size range of feed is not as yet established on a fundamental basis; empirically it is about 2∼3/8-in., and 3/8-in.∼10-m., or about 5 times the smaller diameter; the closer the sizing the better the mill operation.

Apparatus may be anything from a bucket or tub with hand screens to the elaborate small pilot set-up (Fig. 150) described in the American Cyanimid Co. catalogue, in which the separating element is the cone *A*, 20-in. diam. with 70° vertex angle, with a 6-in. cylindrical rim. The cone is truncated near the apex (at 2-in. diam.) and flanged to the down-leg of 2-in. air-lift *C* which delivers sink through splash-head *D* to the sink side of low-head screen *E*. Float overflows the cone through lip *G* onto the other side of *E*. Medium drained from the products at the feed end of *E* combines in hopper F_1 and feeds through leg *J* to 2-in. air-lift *H* and thence through splash-head *K* into medium-funnel *L* carried on column *N*. Medium (new and return) flows from *L* into *N* through slots in the wall of *N*, these slots being of greater combined area than the inner cross-sectional area of *N*. Column *N* extends almost to the bottom of the cone and is open at the lower end; it is rotated slowly by geared motor *O* and carries scrapers to sweep down sediment from the sloping wall of the cone; it is perforated throughout its length with 1/2-in. holes of an aggregate area slightly less than that of the inner cross-sectional area of the column. Pressure on the air-feed lines to the air-lifts ranges from 5 to 10 lb. per sq. in., according to the requirements of the operation. Feed is introduced over the rim of the cone on the side opposite *G*. Mean capacity is about 500 lb. per hr. Results of tests in this plant are given in Sec. 11, Table 94.

Preparation of suspensoid medium. The medium liquid is in all cases (as of 1943) a dilute aqueous solution. The solid is that one of those of Table 68 (it might well be some other) which will float the heaviest material that it is desired to carry over, and which will have the desired density without too great dilution; dilute suspensions require too much agitation to maintain them, and vary too much

in density from top to bottom. Size of the dispersed solid is determined by the settling rate of the suspension and the permissible variation in specific gravity throughout the depth; size also controls the apparent viscosity of the suspension and through this, the time required for test material to sink or float. It is desirable to have a suspension in which specific gravity changes negligibly during the time of test; such suspensions have almost immeasurably small settling rates. A galena suspension having a specific gravity of 3.5, with a change in specific gravity of 0.01 after 1 1/2-hr. standing may be prepared as follows: Charge a laboratory ball mill with <65-m. galena, water, and 1/2- to 3/4-in. balls. Run 24 hr., then discharge the contents over a 1/4-in. screen into a pail. Thicken to a density of 3.5 by settling and decantation of supernatant liquid. Stir the thickened suspension and allow it to stand for 45 to 60 min., then siphon off down to within an inch of the material settled in the bottom. Thicken the material siphoned off to proper density. No difficulties due to high viscosity were encountered in separations using this suspension. Similar procedure applies to ferrosilicon and magnetite. Dispersing agents may be needed in some instances (see Sec. 12, Art. 8).

The principal difficulty in suspensoid sink-float operation is maintenance of the medium. Both light solid and salts from the ore enter the medium; the solid lowers the specific gravity, and the salts may affect dispersion of the medium solid. This matter is difficult to investigate on a laboratory scale because it results from a gradual build-up in circuit. Consequently it is normally left for operation to uncover, with the result that early operation is likely to become mill-scale experimentation unless preceded by fairly large scale long-continued pilot-plant work.

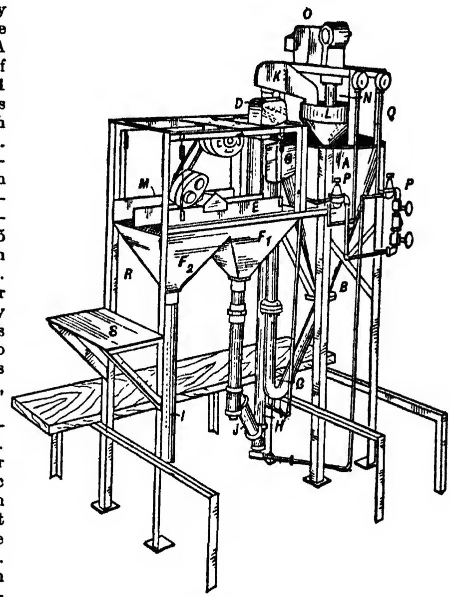

FIG. 150. Laboratory suspensoid sink-float apparatus (*after American Cyanamid Co.*).

Washability tests, similar to those described for coal (see Art. 21), may be made with these suspensions on ores. Table 3 shows the result of such a test on a Tri-State zinc ore. Their interpretation parallels that of the washability tests on coal and need not be repeated.

Magnetic concentration. For small-scale tests for permeability, to remove iron introduced in grinding small samples, or to remove magnetite from pan concentrate and the like, a small electromagnet such as that shown in Fig. 151 is satisfactory.

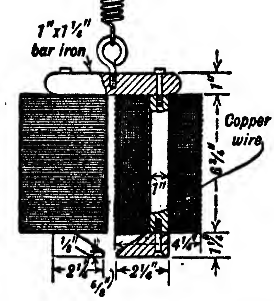

FIG. 151. Electromagnet for laboratory testing (*after Richards*).

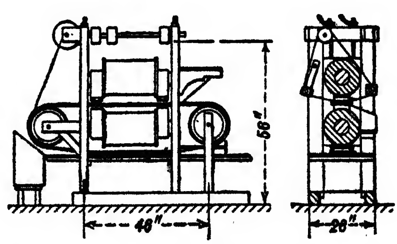

FIG. 152. Laboratory-size Wetherill separator.

Cores and pole pieces should be made of soft iron. The magnet shown, when wound with 5,000 ft. of No. 21 cotton-covered copper wire on each pole, making a total of 6,760 turns, carries a maximum of 0.8 amp. at 50 v. without undue heating. For continuous tests the small Wetherill-type machine shown in Fig. 152 is useful. Each magnet carries 100,000 ampere turns and with proper rheostat control can be used to treat minerals of both low and high permeability.

Davis magnetic-tube concentrator (*Bul 9 MSM*) is useful for concentrating finely crushed ferromagnetic minerals. It consists (Fig. 153) of the C-shaped electromagnet *A* and a glass tube *B* set between the poles at 45°. The tube has the shape of an air condenser with the wide end used for feeding and the narrow end for discharging through a rubber hose, clamp-fitted for control. An upper side arm, similarly equipped with hose and clamp, admits water to the tube.

Procedure. Place 5 to 10 gm. of <100-m. sample (material as coarse as 8-m. may be used) into tube *B*, filled with water, as it rests between pole pieces. As material settles, the upper end of the tube is closed with a stopper. When settled, the magnetic material held firmly to side of tube is washed by passing water through and by moving the tube axially a few inches and at the same time rotating it through a small angle. The wash water, containing tailing, is collected.

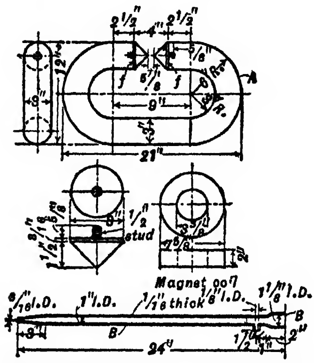

FIG. 153. Davis magnetic-tube concentrator.

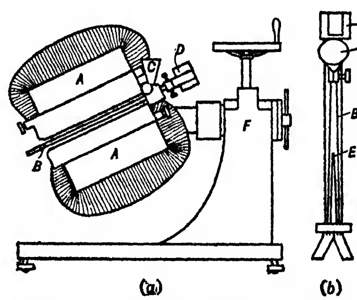

FIG. 154. Franz isodynamic separator.

Franz isodynamic separator (*153 A 563*) consists of an electromagnet *A* (Fig. 154, item *a*) with pole pieces 10 in. long, so conformed as to give an air gap $^3/_{16}$ in. wide at the narrowest place, enlarging to about $^1/_2$ in. at the widest side, and a vibrating chute *B* (Fig. 154, item *b*) on which material to be separated is made to flow from a feed bin *C* by the action of a vibrator *D*. The chute is shallow and of rectangular cross-section, broadened toward the discharge end; it is divided longitudinally by a partition *E*, which divides the flowing material, sidewise segregated by the combined actions of gravity and the magnetic field, into two streams. The magnetic system is carried on a universal mounting *F*, so that it can be oriented in any direction with respect to gravity. The operating variables are magnetic field strength, transverse and longitudinal slopes of chute, and rate of feeding.

The separator operates on material ranging in size from 35- to 600-m. and is capable of diamagnetic separations of materials with 0.3×10^{-6} negative mass susceptibilities (Sec. 13, Art. 1) from less para- or diamagnetic substances. The reported success is ascribed to the specially designed pole pieces, which give a strongly convergent magnetic field, exerting a constant force on a particle of given susceptibility regardless of its position in the field. Gaudin (*ibid.*) has been able to establish differences in magnetic response of some of the more common sulphides.

Flotation Testing

The purpose of flotation testing may be (*a*) to investigate the amenability of an ore to flotation, (*b*) to determine the best method of treatment, (*c*) to investigate a flotation agent, and (*d*) to investigate a process.

Most testing for amenability has been performed with laboratory-scale models of mill cells. The bubble machine (see p. 176), originally designed as a research tool, yields so quickly information of such high diagnostic value that it rapidly pays its way.

Laboratory Flotation Machines

Test tube (or a wide-mouth bottle) may be used for crude, small-scale agitation-froth tests, agitation being effected by hand shaking, and froth separated by introducing an amount of water sufficient to overflow it. A SEPARATORY FUNNEL may be substituted (*111 P 122*), in which case tailing is withdrawn from the bottom without dilution.

Mayeda cell (Fig. 155) for preliminary testing is readily controlled and yields reasonably reproducible results. It is made of glass (Eimer & Amend). The motor-driven stirrer is placed in leg *A* in such vertical position as will induce circulation in counterclockwise direction, as shown in the figure. In operation the cell is placed over a 1,000-cc. beaker, which collects overflowed froth. Capacity is 5 to 10 gm.

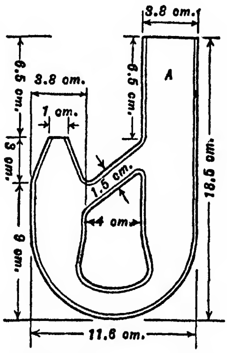

Fig. 155. Mayeda cell.

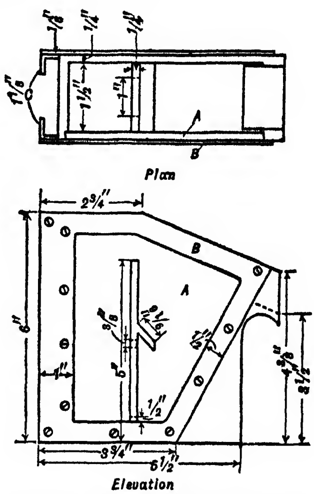

Fig. 156. Minerals Separation-type machine.

Minerals Separation-type machine (Fig. 156) is easily constructed in any moderately well equipped shop. The form shown is fabricated from a block of laminated Bakelite and has one side fitted with plate glass *A*, held on by brass strip *B*, to permit observation. Lugs *C* fit over a tongue on the stand. A laminated-bakelite stirrer is driven by a friction-wheel-type of variable-speed laboratory motor agitator having a speed variation of 100 to 3,000 r.p.m. The machine shown takes an ore charge of 50 gm.

Subaeration cell (Fig. 157), described by Dietrich *et al.* (*RI 3328*), comprises a bakelite box *A*, a stainless-steel grid *B*, steel impeller *C*, and hollow shaft *D*, all mounted on a 2×4-in. post *E* carrying the screw adjusting device *F* for spacing the impeller away from the cell bottom. Speed is about 1,800 r.p.m.; cell capacity, 250 gm. of ore.

All-glass pneumatic cell (Fig. 158) having a capacity of 5 to 20 gm. was described by Knoll and Leaf (*11 IECA 510*). Air flow to the cell is controlled by the arrangement described by Oberbillig and Fahrenwald (*22 MJ 1, 7*). Any air source capable of delivering 4 to 10 liters of clean air per min. is used. A U-tube mercury manometer with a constriction orifice between the arms is used to measure pressure; the constriction is of such size as will produce a 5- to 6-cm. reading with good bubble action in the cell. The adjustable hose clamp *A* is used to regulate air volume. The standard No. 3 sintered-glass disk sealed in the column gives good bubble action and permits of cleaning with sulphuric acid-dichromate mixture. In operation, overflow of froth is maintained by additions of solution at the rate of 2 to 2 $^1/_2$ cc. per min. Table 69 shows typical results obtained with this cell.

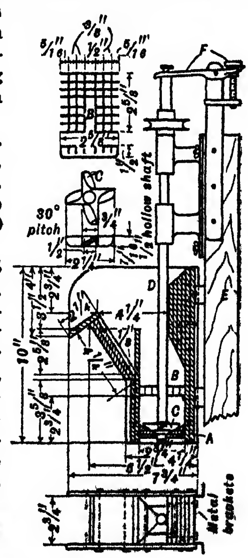

Fig. 157. Subaeration cell.

Tilting pneumatic cell (*87 A 285*) consists of a glass tube *A* (Fig. 159) equipped with a peripheral discharge launder *B* (of laminated Bakelite), held over an air basket *C* (details in Fig. 159*A*) containing a perforated rubber mat or 100-m. screen *D*, through which air is forced, and a movable stand *E* on which is placed a receptacle receiving overflow. The stand *E* may be raised or lowered by moving

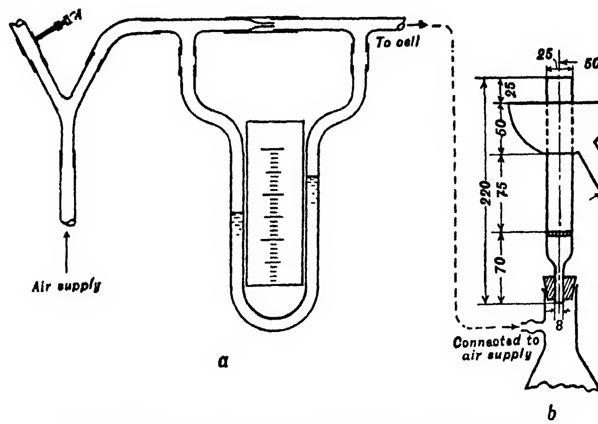

Fig. 158. All-glass pneumatic cell (dimensions in millimeters).

collar *F* which is locked by screw *G*. The tube is held in the basket by a rubber washer *H* under the action of the screw collar *I*. The screen *D*, held between two rubber gaskets, is located between the upper and lower halves of the basket. The basket is held by a side arm passing through a brass tee and locked in any position by action of the knurled ring *J*. The cell has a capacity of 25 to 50 gm. of ore.

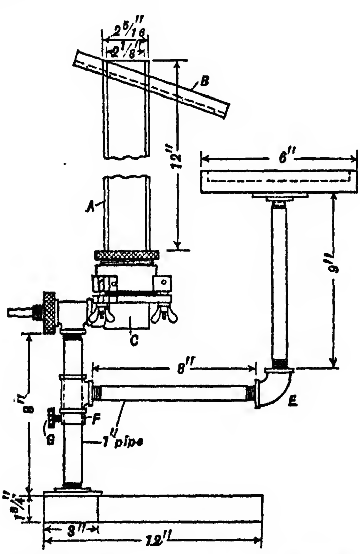

Fig. 159. Tilting pneumatic cell (see also Fig. 159*A*).

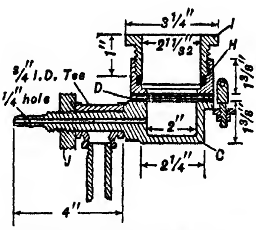

Fig. 159*A*. Detail of air basket for apparatus of Fig. 159.

Laboratory-size models of various mill cells are available from the manufacturers of the commercial units. Such cells have a capacity of 500 to 2,000 gm. of ore.

Bubble machine consists of a camera so mounted on an optical bench (see Fig. 84) as to form an image on a ground glass (or a photographic plate) of the performance at a polished-mineral surface of a captive air bubble, when mineral surface and air bubble are immersed in a liquid contained in a bubble cell preferably all-glass with no cemented joints, measuring 1×4×4-in. inside, mounted on stage *A* of the bubble-cell holder (Fig. 160, item *a*), and there held in position by means of metal clips *B*. The stage, which may be raised or lowered by means of the sub-stage screw *C*, is guided by a beveled block operating in a beveled track cut in ring *D*. Annular ring *D* fits snugly and is free to rotate in a recess cut in the cell holder, and is confined therein by screws *E*. The bubble

Testing Procedure

General considerations. Flotation is still an art of which but few of the basic rules are known. Established operations proceed reasonably smoothly so long as conditions can be kept constant. Plant remedies are mostly mad scrambles to return to normal conditions; they fail miserably in most cases when this is impossible. With such a background, much of flotation test procedure is of the same cookbook nature, and favorable results, when the problem is in any way out of the ordinary, are largely dependent on the law of probability.

The primary reason for this state of affairs is that most flotation testing is done by empiricists, whereas flotation is a complex physicochemical process, the controlling phenomena of which lie in the relatively new field of surface chemistry. Here most of the laws are in the making; few have yet got into the books in workable form; and the books are not in the standard curricula. Progress has been as rapid as it has because Edisonian search by large numbers is bound to turn up something, and further because the soaps and sulphydrates are such powerful and generally active reagents that they will ordinarily do something despite the worker.

Basic rules of flotation. A half-dozen basic rules are known to a dependable extent.

1. With the exception of a few hydrocarbon-containing minerals, an air bubble in water will not adhere to a mineral particle unless the particle is coated with a hydrocarbon-bearing film. It follows that when unwanted particles appear in the froth, except when carried mechanically and not attached to air bubbles, they are so coated; and that when

wanted particles fail to appear, they are either not so coated, or they or the air bubbles carry additional coatings.

2. Formation of hydrocarbon coating on nonhydrocarbon-bearing minerals is, with a few exceptions, the result of a chemical reaction, normally of exchange type. The known exceptions are graphite, sulphur, molybdenite, realgar, bismuthinite, and stibnite. These minerals can be coated by neutral oils. Certain metallic minerals are coated by amines by an addition-type reaction. All other minerals require ionizable hydrocarbon-bearing collectors.

3. In flotation pulps, dispersed particles are water-wetted; in all cases where their surface condition is known, the surface is ionized; they will not adhere to an air bubble. Nondispersed particles may have ionized surfaces also; if they have, they will not attach to air bubbles. Particles flocculated without the intervention of a gas or a second liquid phase may have either ionized or nonionized surfaces. In the former case solubility will be high enough to permit leaching away enough ions for a test; in the latter case the mineral will not, in all probability, react with any collector.

4. The surface composition of minerals with surfaces ionized in a flotation pulp can be changed substantially, by ion exchange, with any ion, organic or inorganic, present in low or high concentrations, which forms with one of the ions of the mineral a compound less soluble in the pulp than the original mineral. Minerals with un-ionized surfaces cannot be changed by ion exchange with an ion present in low concentrations; they may be changed by exchange with high concentrations of introduced ions; they can frequently be changed by low concentrations of oxidizing or reducing agents.

5. An ore pulp is a veritable chaos of ions, collected by the water from the atmosphere; from its sources, immediate and remote; from the ore; and from the mill. It is an important function of the conditioning agents to bring order; by suppressing some ions, and/or supplying others with such powerful beneficial effects that they override the harmful ones.

6. All or substantially all of the actions at particle surfaces in a flotation pulp are ionic in character and hence obey the laws of mass action. The constants for the surface-reaction zones are unknown, as are also the concentrations of reactants there. But from a practical standpoint the direction of reactions can be predicted effectively by considering the bulk concentration of the reactant in solution, and can, therefore, be controlled by control of this concentration.

It follows from these rules that intelligent flotation testing is more of a research job than a routine testing job. As such, it necessitates careful and detailed recording, during the course of the test, of every feature connected therewith, special note being made of all conditions surrounding any unusual performance. Although routine procedure can be standardized to the point where different operators can check each other on duplicate tests, it should not be concluded that this reproducibility represents control through complete knowledge; the frequency of occurrence of the unexpected is still great enough to contradict such a conclusion.

Primary factors affecting flotation are: (1) the mineralogical character of the feed; (2) size distribution of the feed; (3) method of comminution, and the time elapsed between each successive size reduction; more generally, the previous history of the ore from mine to testing laboratory; (4) pulp dilution; (5) the amount and character of organic and inorganic material put into solution by the ore; (6) the amount and character of added flotation reagents, the order of addition, the time elapsed between additions, and the nature and duration of the operation practiced between additions; (7) the flotation machine; (8) the degree of agitation; (9) the amount of added air; (10) the duration of treatment at each stage; (11) the temperature.

Records of tests should be as complete and explicit relative to the above factors and to the indices of their effects as it is possible to make them. Effects are indicated by volume and character of froth; amount and kind of solid load; degree of dispersion of the pulp; rate of flotation, and finally recovery and grade of concentrate. Records of tests are best kept on a printed or mimeographed form that calls specifically for the information desired. The form should include at least the following items: TEST: number, date, purpose. FEED: origin, history, approximate mineral composition, sizing test, assay, record of microscopic examination, weight. MACHINE: type, size, structural materials in contact with pulp. WATER: source, *p*H. REAGENTS: name, quantity, order of adding, method of mixing, duration of mixing period; pulp density, temperature, and *p*H during mixing. ROUGHING (or concentrate-making period): duration, degree of agitation or aeration, pulp density, temperature, and *p*H; character of froth, including texture, size of bubbles at water line and overflow level, elastic or effervescent nature of bubbles, consistency of froth mass, persistence, mineralization, *p*H, percentage of solids. CLEANING (middling-making period): collect the same data as in roughing. ROUGHER TAILING: *p*H, degree of dispersion, relative rate of settling, temperature, density. CLEANER TAILING: the same. ASSAYS AND DERIVED METALLURGICAL RESULTS. NAME OF OPERATOR. It is well to define the meaning of certain of the descriptive terms. The following definitions are useful. TEXTURE: Examine the "grain" of the froth. Mental reference to the grain of a rock or other nonhomogeneous mixture will

help in choosing the proper descriptive term. The texture should be described as *even* when all or a great majority of the bubbles in a given horizontal line against the glass walls of the testing machine are of approximately the same size; *uneven* describes the reverse condition. Texture should be described as "fine" when the average diameter of bubbles at 1/2 in. above the water line is 1/8 in. or less. CHARACTER OF BUBBLES: *Elastic* indicates that the surface bubbles in the machine are relatively persistent, that they may be deformed considerably without bursting, and that they elongate markedly in overflowing; *effervescent* bubbles burst with considerable violence soon after reaching the surface layer. Quality is *viscous* when patches of the froth act almost as solids and the body of froth is sluggish in the cell; *tender* describes a homogeneous fluffy froth that is active on the surface of the cell. MINERALIZATION is best determined by examining a film under a low-power (15 to 20×) microscope. *Heavy* describes the mineralization of a film that is crowded with solid, opaque, and draws back slowly when punctured; *light* describes the complete reverse of this condition; *medium* describes a wide intermediate range. *Gangue* and *mineral* indicate the predominating mineral in the solid load. PERSISTENCE: *High* describes an overflowed froth that shows little or no tendency to break down after standing, say, 2 or 3 min.; *medium* describes a froth that breaks down spontaneously to about one-half its volume in 1 or 2 min. after removal; *low* describes substantially complete breakdown in 1 min. SETTLING RATE of tailing gives a pseudoquantitative measure of degree of dispersion. It is best measured by allowing 1 min. to elapse after flotation ceases, then measuring the distance from a fixed point on the side of the machine to the top of the subsiding solids, and measuring again after the lapse of 1 min. For more direct observation, examine a sample at 100×, using dark-field illumination.

An experienced operator can keep such a record on a prepared form with very little more time than is required for the test itself; it serves as a guide to methodical and careful observation; and it makes it possible for persons who have not seen the test to visualize the performance and interpret the results. There is definite correlation between many of the indices and the metallurgical results; when it does not appear, it is time for the director of test work to begin inquiries; there is a discovery of some kind in the making.

Preparation of a machine for testing is solely a matter of cleaning. Procedure in cleaning varies with the materials of construction and with the previous use of the machine. In general, scrubbing with a strong solution of sodium carbonate, followed by a blank run with finely ground ore, a neutralizing wash with dilute hydrochloric acid, and another blank run with finely ground quartz, will clean up the usual metal machine. If previous use involved a hydrocarbon oil, a preliminary wash with benzene, followed by alcohol, should be given.

Reagent additions may be made in a number of ways. Mohr pipettes give accurate control of reagents; their chief drawback is the difficulty experienced in filling them under hurried test conditions. Calibrated medicine droppers are useful, when the volume to be added is neither too large nor too small; 5 to 20 drops is a good range. Calibration changes with the surface tension of the liquid, hence droppers must be calibrated for each liquid with which they are to be used. Some operators prefer to use a pendent drop formed on a wire; a straightened paper clip, one end of which is embedded in a cork of suitable size, serves admirably; it must be calibrated for different liquids. Luer tuberculin syringes (*140 #11 J 55*), which are available in sizes from 1/4-cc. to 50-cc., are easy to control; 1 @ 2-cc. and 1 @ 10-cc. covers the necessary range; interchangeable stainless-steel needles ranging from No. 15 (large) to No. 26 (small) are available for them. Solid reagents are best added in solution, if possible; otherwise they are weighed in. All quantities are most conveniently measured in metric units; tables may be prepared giving conversion from cc. or gm. of reagent to lb. per ton of ore.

Preparing ore charge. The method depends upon the ore, the nature of the test, and the nature of the reagents. General practice is to crush the original sample dry through 10-m., and follow by wet grinding in a ball mill of suitable size for such time as produces the desired fineness. Although this procedure does not parallel mill practice, where ball-mill feed is rarely less than 1/4-in., it is adopted because laboratory mills cannot be fed at this size and still make a product free from oversize and undue slimes. The procedure thus exposes a larger surface area of mineral to the air than is exposed at the same point in mill practice.

With easily oxidized ores, such as those high in pyrite or pyrrhotite, this exposure is detrimental. Thus (*32 CIMM 318*) galena was mixed with (*a*) silica, (*b*) pyrite-silica, (*c*) pyrrhotite-silica, and (*d*) marmatite-silica, dry ground, split into samples, a part wetted and all samples permitted to stand for 48 hr. The silica mixture (*a*) was not affected, as evidenced by flotation tests. The iron mixtures showed decreased recovery of galena and required more xanthate for flotation; the pyrrhotite-silica-galena mixture gave poorest recovery. With such ores, therefore, grinding should follow crushing immediately.

Although dry grinding may be practiced with impunity with some ores, it is generally unsatisfactory. Tests on dry-ground samples often give recoveries 10 to 20% lower than those on wet-ground samples (*RI 3328*). It seems advisable, therefore, to practice wet grinding, simulating mill conditions, even though it can be established in particular cases that wet grinding produces no essential changes in results.

Ball-mill grinding procedures vary. BATCH GRINDING is usual unless a particular mill condition is being simulated. Capacity of a batch mill should closely approximate that of the flotation cell; for mill-index tests this ranges from 500 to 2,000 gm. The method of flotation testing may also control the charge, as when concentrate cleaning is contemplated for ores with a large ratio of concentration, since better results are obtained

with the larger charges. Fahrenwald (*Deco Index 112*) recommends choice of mill and grinding conditions such that reduction to flotation size requires 10 to 15 min. This is within the range of ordinary grinding time factors. Many operators simply determine the time required for a particular ore to produce the required grind, making no attempt to keep the grinding time within limits. Standardization of pulp dilution, ball size and load, and speed of mill is invariably practiced. In many laboratories the grind is performed in pebble mills to avoid introducing unknown amounts of iron into the sample, and a ball-mill grind is run in parallel to study the effect of iron. Laboratory ball-mill grinding introduces more iron than is introduced in mill practice; but laboratory pebble-mill time-factor is definitely longer than plant time-factor. Choice depends on the ore and the purpose of the test.

Distilled water is commonly used in laboratory grinding. Experience has shown this to be the safest practice in preliminary and general testing because mill waters and tap water contain soluble and insoluble substances (see Table 70), in amounts varying from day to day, which materially affect flotation results. The effect of acidity or alkalinity of ordinary water may be overcome by the addition of a suitable neutralizing agent. The effect of the soluble and insoluble substances is not so readily counteracted, for it may not be detected and if detected may not be understood; yet these materials may produce tremendous changes in results. Small amounts of ferric hydroxy sol can activate quartz so that it can be collected by oleic acid. When application of test results to mill operation is contemplated, final testing should be done, using water available at the mill site. In testing nonsulphide ores with oleic acid as collected, distilled water should always be used; hard waters can be softened to substantial equivalence with lime-soda or (preferably) zeolite (*RI 3370; 3437*). If the soluble salts from the ore are known to have an adverse effect on flotation results, the ground ore should be washed with distilled water, and distilled water used in flotation.

Table 70. A troublesome mill water in the Tri-State district (*RI 3149*)

Constituent	P.p.m. *a*

*p*H	<3.0

a Parts per million parts of water, or milligrams per liter.

A somewhat oxidized lead ore containing small amounts of sphalerite, siderite, and pyrite in a gangue principally dolomite, with smaller amounts of calcite and glauconite, when ground to flotation size with distilled water, yielded a solution of the following salt content: 17.3 p.p.m. of bicarbonate alkalinity as sodium bicarbonate; 44.3 p.p.m. of lime; 56.0 p.p.m. of magnesia, and 86.4 p.p.m. of sulphate (*RI 3214*). These concentrations are not excessively high; subsequent testing showed them to have little effect on results in sulphide flotation.

If reagents are added to the ball mill, it is wise and informative to examine the pulp and compare it with a similar grind using only distilled water. The *p*H of a filtrate of the product should be determined. It should also be examined under the microscope to determine extent of dispersion; if flocculation is noted, its selectivity, if any, should be ascertained. Simple settling tests and the effect thereon of additions of lime, sodium silicate, etc., are recommended, for the yield in information is a better than fair return for the investment in time.

Laboratory closed-circuit grinding, simulating practical operation, comprises a series of short-period grinds, followed by screening or (preferably) classification to remove the finished product. The unfinished material of each stage is returned to the mill together with enough new feed to compensate for the loss in weight due to removal of finished product. The unfinished material which constitutes the circulating load may be controlled by the duration of the short-period grind.

Other laboratory grinding techniques may be used according to the plant operation that is being simulated.

Testing mill pulps. When the test sample is already ground, *i.e.*, a mill pulp, it should be tested as soon as possible because its state of dispersion may change with time and changes in temperature. It should not be dried prior to test and should be kept in a container, preferably glass, which does not introduce appreciable amounts of foreign ions into the pulp; this is especially important with nonsulphide pulps.

Pulp dilution in flotation testing usually ranges from 20 to 25% solids by weight, though pulps containing as high as 50% solids are sometimes used. Pulp dilutions ranging from 6 to 12% are used in cleaning operations (see below).

Flotation procedure varies with the type and design of machine. The following is a composite which may be altered to suit a particular machine. Ball-mill pulp is transferred to the flotation cell, which is in operation, with as little water as possible. If the cell is equipped with an air valve, this should be closed. If a conditioning agent, other than an activator or depressant, is used, it is now added. After a $^1/_2$-min. interval of agitation, other conditioning agents, if any, are added, followed by a 2-min. period of agitation.

Collector is added next, immediately followed by the frother. After about 2 or 3 min. of agitation, water is added to bring pulp up to proper dilution, at which time the pulp level is 2 or 3 in. below the overflow level. The air valve, if any exists, should now be opened.

If stage collection is practiced, as is normal in nonsulphide flotation, when slimes are present, collector is added in minute amounts in several stages, each stage being followed by skimming of froth; it is not necessary or usual to agitate for more than 10 to 20 sec. after the reagent additions.

Concentrate is removed with the aid of a paddle until some predetermined time has elapsed or until an end point, as indicated by color changes, loading, etc., is reached. The method of skimming depends on the test; for roughing purposes the froth is scraped deeply, whereas in cleaner operations shallow scraping is practiced. It is helpful, though not necessary, to make provision for continuous addition of water to the cell so that the pulp level remains constant. The added water may contain frother in a somewhat higher concentration than was originally present in the cell.

The procedure described may be used to make (*a*) low-grade concentrate and a clean tailing, by skimming the froth deeply and quickly in the endeavor to produce a low-grade tailing; (*b*) finished concentrate and a relatively high grade tailing by slow, shallow skimming so as to allow maximum cleaning in the froth column; (*c*) a finished concentrate, a middling, and a finished tailing, by shallow, slow skimming to give concentrate, followed by rapid, deep skimming, to give finished tailing.

Grade of concentrate can ordinarily be improved, if poor, by decreasing the rate of froth overflow. This is accomplished by decreasing aeration, diluting the pulp, using less or a less-powerful frothing agent, by eliminating an agent that stiffens the froth, by choosing an agent that is more highly selective, or by the use of dispersing agents such as water glass, quebracho, and certain inorganic salts.

Recovery will usually be increased by increasing rate of froth overflow. This may be done by increasing aeration, increasing percentage of solids, using more frothing agent or a more powerful frothing agent, or adding a froth stiffener. Recovery may also be increased by increasing selection, either by the use of a different collecting agent or by adding a dispersion agent.

Locked test (*RI 3328*) was devised to minimize the in-process middling in batch testing. Fig. 161 gives the flowsheet of a four-batch test using two stages of cleaning without middling regrind. While the flowsheet as drawn gives the impression that the process makes only the two desired products, concentrate and tailing, it is clear that the underflows of stages 4C and 4RC are not changed from middling character simply by routing them to the tailing line. It is less apparent, but nevertheless true, that either the tailings 2S, 3S, and 4S contain middling, or it is cumulated into the 4S middling product, which is also shown routed to final tailing. A truer picture of the operation is given by the dotted lines leading to the product M.

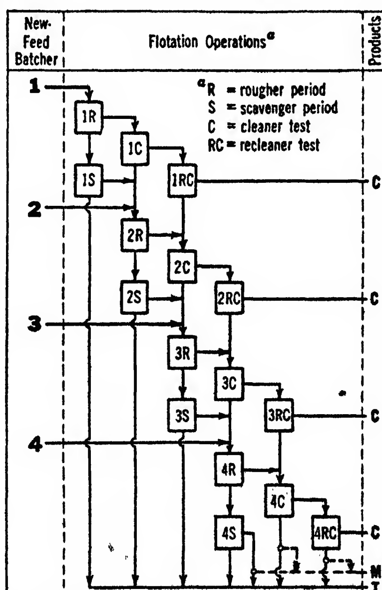

FIG. 161. Flowsheet for locked test.

If the middling is locked middling, it may be returned to the ball mill, provided such return does not introduce difficulties with reagent control and order of addition. Reagent control is difficult at best, because of the introduction of unknown proportions of reagents to each successive batch. This is particularly true of frothers and conditioners, especially if they possess a cumulative effect.

TIME required for such a test depends upon the number of cleaning stages and the number of batches; it ranges from 8 to 10 hr. Easily altered ores may undergo sufficient change during such a time as to invalidate results completely. The test bears no resemblance to any mill flowsheet. It is questionable whether in any case it approximates mill results any more closely than the standard batch test.

If differential flotation is to be practiced it may be done by (1) straight flotation separation on the original pulp, removing first one mineral, then after the addition of suitable reagents, removing the second mineral, etc.; (2) first making a bulk concentrate of the two or more minerals, followed by subsequent differential flotation of the bulk concentrate. The effect of changes in particle size upon the results of differential flotation is marked and should be studied.

Oxidized and nonsulphide ores. Heavy-metal sulphide ores are easily handled with the above described procedure. Oxidized metalliferous ores as well as the nonsulphide ores require a more refined technique. If sulphidization is practiced with the oxidized metalliferous ores, the time required for testing should be kept to a minimum since the sulphide coating reverts easily and quickly to the

oxidised form. Flotation prior to sodium sulphide addition followed by sulphidisation of the resulting tailing yields good laboratory results. With the nonsulphide ores close control of pH and complete avoidance of heavy metal ions in the circuit should be practiced. A flotation cell constructed of nonmetallic parts is recommended.

Table flotation (Sec. 12, Art. 30) is highly effective on relatively coarse deslimed pulps, and should always be considered when mineral frees at sizes from 10-m. down, particularly if such freedom is complete, as is often the case with residual deposits. Procedure comprises thorough desliming, the use of oils as secondary collectors (Sec. 12, Art. 6), conditioning through the point of oil coating in a thick pulp, dilution, and separation on a surface such as a Wilfley table, where the oiled pulp is spread out in a thin layer, and turned over well to permit oil-air agglomerates to work to the surface and discharge in a cross stream of water. Applicability can be tested in the laboratory with a beaker and stirring rod for oiling and a large watch glass or a pan for separation. Plant practice has been largely on pebble phosphates with shaking tables for separation (Sec. 3, Figs. 52, 53). Other examples reported are calcite from quartz (*RI 3247*) and sylvite from halite (*RI 3271*). Table operation is in no way different from normal (Sec. 11, Art. 22).

Testing for amenability should be preceded by microscopic determination of the approximate qualitative mineralogical composition and state of the ore as regards oxidation. Preliminary examination with a binocular microscope followed by study of a polished section, supplemented, if necessary, by study of a thin section or some fragments with a petrographic microscope, will usually save time and permit much more intelligent prosecution of the actual testing work. If microscopic study shows unaltered sulphide of known amenability associated with the ordinary rock-forming gangue minerals, it is a safe conclusion that the ore is amenable to flotation and actual tests in the machine may be directed rather toward determination of the best method of treatment than toward confirmation of amenability. If miscroscopic examination shows mixed sulphides, that fact will indicate low-grade concentrate and point the way toward differential flotation. If there are signs of oxidation, trouble is to be anticipated and the question of amenability cannot be answered without actual flotation testing. If the examination reveals minerals of unknown amenability, then the following systematic procedure is recommended. This procedure is not to be looked upon as inflexible or complete, but merely as the starting point for what is usually a long and arduous search.

Test-tube testing. The chemical composition of the mineral that it is desired to float is ascertained. A search is instituted to determine whether the anion or cation of the mineral or its surface alterations form insoluble compounds with collector-type reagents (Sec. 12, Art. 3). If the literature does not provide an answer, simple test-tube experiments using solutions of these ions to which are added collector-type reagents may be used. If visible precipitates are formed, evidence of compound formation between the ion and the collector is at hand and confirmatory testing with the bubble machine is in order. The chemical testing should be performed by an operator having a considerable background in chemistry. Should such test-tube experimentation fail to give an answer, as it well might because it assumes the surface condition of the mineral, testing with the bubble machine is the next step.

Procedure for bubble-machine testing. A specimen of the mineral is rough ground to suitable dimensions, *e.g.*, in the range $1 \times {}^1/_2 \times {}^1/_2$-in. to ${}^1/_4 \times {}^1/_4 \times {}^1/_4$-in. If the specimen is too small to handle on a polishing lap, it may be briquetted and the exposed surface polished to a high finish on ordinary laps. The laps used in surfacing for bubble-machine testing are cloth-covered aluminum or glass laps, since it has been found that the metal used in customary laps may produce activation of some mineral surfaces. Re-levigated alumina is used for polishing. To test a particle, it is cleaned on the test lap with copious additions of tap water until, when removed therefrom, the surface remains completely wetted by water; if water draws back, the surface is contaminated and should be further polished. The particle is then transferred quickly to a beaker containing a solution of the presumed collector, and is conditioned therein for about 5 min. Beaker and contents are then placed near a stream of distilled water running into and overflowing the bubble cell, and the particle is transferred from beaker to bubble cell, using fire-cleaned platinum-tipped tongs, in such fashion that it never crosses an air-water interface. The outside of the cell is dried and the cell is placed on the stage of the bubble machine. The bubble holder is placed in position with the cup under water and an air bubble is placed on the bubble cup by means of a medicine dropper with tip curved back 180°. The verniers actuating the block in which the bubble holder is held are used to center the bubble relative to the field and particle. A sharp image of the bubble is produced on the ground glass by means of the lens-focusing device. The bubble is then lowered until it touches and is compressed against the particle. It is allowed to remain in this position for about 1 min., then the bubble-holder is slowly raised and the behavior observed on the ground glass. A negative result is obtained when the bubble comes off cleanly, without any evidence of clinging to the surface. If cling is noted, and lack of cleanliness in procedure is suspected, the test should be repeated. If clinging persists, bubbles of smaller diameter should be tried; if the tenacity of cling increases with decrease in bubble diameter, the polished, conditioned mineral particle should be placed under water in a petri dish and the dish put in a vacuum

machine (Fig. 162). The cell is evacuated and the surface of the particle observed using a low-powered binocular resting on the cover plate. Formation of bubbles at the surface of the particle is evidence of the exisistence of a small though definite contact angle. Large contact angles may be measured (Fig. 163) on the ground glass by means of a protractor applied to a base line determined by the extreme points of coincidence of the bubble and of its image mirrored by the particle surface. The angle included between this base line and the tangent at the triple-phase contact point is called the contact angle. The bubble machine test requires about 10-min.; it may be shortened somewhat by filling the bubble cell with collector solution and testing for air-bubble contact therein. When differential flotation is contemplated, particles should be conditioned for bubble testing in the solutions in which it is contemplated to float or depress them as the case may be. If the bubble test is made in

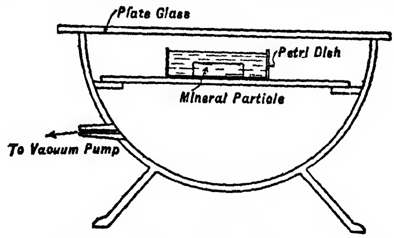

FIG. 162. Vacuum-test machine.

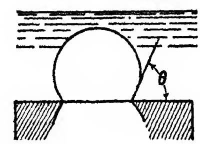

FIG. 163. Contact-angle measurement.

solutions, coating of the surface by sedimentation must be guarded against. The surface may be swept with a captive bubble, or may need to be rubbed with a clean cotton swab or the like. When the collector-coating compound is relatively soluble, as with amines, the contact-angle test must be made in the conditioning solution.

Confirmation of bubble tests by actual flotation may at first produce poor or completely negative results. These may be due to slime coating of the mineral to be floated, reagent consumption or destruction by soluble substances put into solution by the ore, reagent consumption by the ore slimes, alteration of the surface properties of the mineral by soluble substances, etc. Test procedure should now be directed toward determination of the origin and correction of the trouble. If flotation tests alone had been used as a test of amenability, the same negative result would have been obtained, and the investigator would have concluded that the particular collector used was inapplicable to the ore under test. Hence bubble-machine testing, in addition to eliminating this pitfall, points the way for further testing designed to improve results.

Commonly used flotation agents, together with their function in the flotation cell, are listed in Sec. 12, Arts. 4, 5, 10, 12.

Tests for a method of flotation are in no way fundamentally different from tests for amenability; they differ only in that they are more thorough and exhaustive and should, ordinarily, be carried out on a larger scale. They should start with knowledge of amenability and of one method of treatment, and should comprise investigation of the effect on recovery and grade of concentrate of changes in flotation machine, in grinding, dilution, reagents, temperature, water supply, etc. The bubble machine can be used to advantage in following the effect of changes in concentration and nature of reagents, and in temperature. The following facts should be kept in mind in this testing campaign:

(*a*) In the laboratory the agitation-froth process is easier to control and tests are more quickly run than by the pneumatic process.

(*b*) An ore that can be concentrated in an agitation-froth machine can be concentrated, with certain changes in the accessory details of operation, in bubble-column machines, and *vice versa;* but in general, flotation can be made more intense in the agitation-froth machine, while the bubble-column type is capable of more delicate control.

(*c*) Before a mill is built, the process worked out in the laboratory should be tried out on something approximating mill scale in a pilot plant, especially when the mineral and gangue are close together in floatability, for it then becomes crucial to determine the effect of returned middling.

(*d*) Flotation operates most easily and with greatest leeway on a pulp containing from 15 to 20% solids. On the other hand, power consumption, mill equipment, and reagent consumption are lessened as the percentage of solids in the pulp is increased. A part of the advantage of thick pulps can be utilized by conditioning in thick pulp and diluting to float; this is particularly true when oily collectors are used.

(*e*) Change of reagents in an operating mill may be a serious matter, involving considerable laboratory experimental work and costly interference with mill operation. Hence the reagent chosen should be one of which a supply at a fair price is reasonably assured, and the reagents tried in the testing work should be of this class. Such a list includes petroleum oils, pine tars, coal tars, coal-tar creosotes, xanthates, Aerofloats, thiocarbanilid, fatty acids, some amines, pine oil, cresylic acid, alcohol mixtures in the C_7 to C_{14} range, soda ash, lime, sodium silicate, caustic soda, sodium sulphide, alkaline cyanides,

quebracho, starch; certain detergents of the types including sulphonated alcohols, salts of multibasic inorganic acid esters of long-chain organic acids, and halogenated oils; zinc sulphate, sodium sulphite, and copper sulphate. Certain other substances may be locally abundant and their use, temporarily at least, may be justifiable on that score, but a suitable flotation agent consisting of one or more of the above-mentioned substances should be determined and the best available supply investigated against the time when the supply of the local substance is exhausted.

Testing flotation agents is probably the most common type of testing at an operating plant. The first step is, of course, to find by actual test, first in the laboratory and then in the mill, whether the new agent will produce satisfactory recovery and grade of concentrate with the mill feed. In this investigation it is essential that the conditions of contemplated use be duplicated. This is not always an easy matter. For example, if flotation feed is reground residue from gravity concentration, if reclaimed water is used in the mill, and the new reagent is to replace one or more of the reagents in regular use, it is substantially impossible to obtain a sample for laboratory testing that has the size and mineralogical composition of mill-flotation feed and is uncontaminated with existing reagent. Under such circumstances the best approximation to mill conditions will be attained by taking some of the original ore, concentrating it in the laboratory by gravity treatment patterned on the mill scheme, then grinding the residue in the laboratory to mill size. It is not safe to take a sample in the mill and dry it to drive off mill reagents. Such dried pulp will almost invariably float more poorly than properly prepared fresh pulp.

Assuming favorable flotation results from the laboratory tests, the questions of quantity required, supply, and price should be investigated. Unless the potential supply is large, the price is sure to advance with adoption of the agent by other companies, and deliveries may be difficult. The probable effect of storage at the mill should be looked into; the behavior in the water-recovery system; and the effect on flotation of such part of the reagent as comes back with reclaimed water. Some reagents that have been suggested and/or used have unpleasant or dangerous physiological effects, *e.g.*, amyl acetate, valerianic acid, hydrogen sulphide, sulphur dioxide, and alkaline cyanides. This fact must be given due weight.

When a new reagent is proposed to be used in combination with old reagents, the laboratory investigation should include parallel runs in which every condition is the same except that in one run the proposed new reagent is present and in the other it is absent. A considerable number of reagents have been patented that will not stand this test.

Testing flotation processes involves no different principles, in so far as determining suitability for mill operation is concerned, from those already outlined. If the process is a new one, it is well to bear in mind that the inventor may know little about it himself and that, unfortunately, he does not always put all of that little into his patent. As a result the early trials may be a succession of failures. The history of the agitation-froth process typifies the first contingency. The discovery was made in treating high-grade zinc-bearing tailing in Australia. Great difficulty was encountered 5 years later in applying the process to Butte zinc ores, and its subsequent application to low-grade copper ores was established as the result of literally thousands of trials by mill operators in the face of statements by representatives of the patentees that their process was not suited to the treatment of such ores.

When testing is directed toward establishment of the physical and chemical phenomena underlying a flotation process, actual operation of the process is of little avail. The essential phenomena involved lie in the field of molecular physics and chemistry, and, in the operation of the complete process, are so complex and masked that it is impossible to segregate and observe them. Such testing requires resources both of equipment and personnel different from those available at a plant laboratory. The experiments usually bear but little apparent resemblance to the process. The danger to guard against is that of overlooking, in a simple experiment that involves only one of the elements, the effect of the simultaneous action of the other elements.

Interpretation of test results. Translation of laboratory results into terms of mill-scale operations is, in the usual case, less difficult in flotation than in gravity concentration, and in all cases more certain than where chemical reactions such as occur in leaching and precipitation operations are concerned. Any flotation result that can be obtained in a laboratory machine can be obtained in mill operation, if the essential laboratory conditions are duplicated. The converse of this statement is also true, except that the mill-sized machine is capable of handling a somewhat coarser feed than can be handled in the laboratory machine. Considering the essential elements of pulp treatment in detail, the translation from laboratory results to mill results will be as follows:

Average size of feed may be slightly coarser in the mill than in the laboratory or, if the grinding in the mill is carried to the same extent as in the laboratory, a somewhat better result, other conditions being equal, may be expected in the mill than in the laboratory.

Water may make a considerable difference between laboratory results and mill results and this difference may be either in favor of or to the detriment of the mill. The former will ordinarily be the case if a portion of the mill water is reclaimed and reused. Under these circumstances it will ordinarily be found that the flotation agent brought back by the mill water will decrease, to a considerable extent, the amount of new flotation agent that it is necessary to add, and that froth will be more easily obtained with this reclaimed water mixed in. If, however, there is any considerable amount of soluble salts in the ore, or if the settling ponds are of considerable area and in an arid region, and there is any considerable amount of dissolved solids in the new water or thrown in by the ore, then the salts in the water may have a harmful effect on flotation.

Flotation agents in the mill will be the same as in the laboratory except that it will generally be possible in the mill to reduce, to some extent, the proportion of frothing agent in the mixture.

Peripheral speed of the agitators in agitation-type machines may, in general, be somewhat less in the mill than in the laboratory.

Air consumption per cubic foot of pulp treated in pneumatic machines will usually be less in the mill than in the laboratory. The pressure on the underside of the blanket will necessarily be higher in the mill machine than in the laboratory machines described, on account of the greater head on the pulp side of the blanket.

Time of treatment necessary in the mill will approximate closely the time for making a given recovery and grade of concentrate in the laboratory. Grade of final concentrate obtained in the mill will be close to that obtained in the laboratory. With oxidized metalliferous ores requiring sulphidization, plant results are usually better on account of rapid reversion of the sulphidized surface in the laboratory tests. Recovery will come close to the indicated extraction calculated by formula 133, from laboratory results, if, in the calculation, the figure for grade of concentrate is that obtained from the cleaner operation, the figure for rougher tailing is that obtained from the rougher operation, and the middling or cleaner tailing obtained in the laboratory is disregarded, provided that the grade of this middling product is not more than twice the grade of the original heads, and that the mineralogical character of the middling is not markedly different from that of the original feed.

Accessory Laboratory Equipment

In addition to equipment of the nature described in connection with specific test methods, an ore-testing laboratory should contain miscellaneous equipment of the nature listed below:

Sample driers. A useful form for large samples is shown in Fig. 164, item *A*. It consists of a large 3-walled rectangular pan with a steam chamber for a bottom, all mounted on a suitable framework at a convenient distance from the floor. The steam drying rack (item *B*) and gas drier (item *C*) are suitable for smaller samples. An enclosing cupboard with good ventilation is essential to the best performance of these latter apparatus.

Hand-sampling equipment. Square-edge D-handle shovels. Cross for cone-and-quarter sampling. Jones riffle with about 16 @ 1-in. chutes and another with about 16 @ 0.5-in. chutes. (The riffles should have an even number of chutes.) Galvanized ash cans, coal hods, and pails. A cement sampling floor free from cracks or 2 @ 1/4-in. steel sheets about 6×6-ft. Floor brush. Coffee mill. Disk pulverizer.

Assay laboratory with full equipment of apparatus and reagents for both wet and dry assaying. See a good book on assaying (Art. 10) for a check list. There should be gas-fired pot and muffle furnaces that will serve also as roasting furnaces for testing in magnetic concentration and hydrometallurgical work.

Microscope equipment. Hand lens, 10× to 15×. Microscopes (see Art. 9). Grinding and polishing laps. Mounting equipment. Apparatus and chemicals for microchemical work. See Chamot, Murdock, Davy and Farnham, Johannsen, Art. 10.

Equipment for sizing tests. Set of 8-in. Tyler standard sieve-scale testing screens to $\sqrt[4]{2}$ ratio up to 1.050 in. (see Table 28) and square-mesh wire screens in wooden frames about 18-in. square on approximately $\sqrt{2}$ scale from 1.05-in. to 4-in. Testing-sieve shaker. Sample pans, 2-, 4-, 6-, 8-, and 12-in. diameter (patty tins and pudding tins will serve). Scoops. Counter brushes. Round assay-button brushes. 1-in. flat camel's-hair brushes. Glazed paper. Paper bags and sample envelopes. Eye piece and stage micrometers for the microscopes (see *Microscopic sizing*, Art. 15). Elutriation apparatus (see Arts. 13, 14). Sedimentation equipment (Art. 16).

Grading equipment. Mechanical classifiers of suitable size for the ball and rod mills. Diaphragm cones for feeding concentrating tables. 6×6-ft. Dorr thickener with diaphragm-pump discharge.

Handling equipment. Trucks, conveyors, elevators for dry material, and centrifugal pumps for fine wet material.

Miscellaneous. Good equipment of tools for simple carpentry, plumbing, tin-smithing, and machine work. Racks for storage of material and small samples. Room for barrel or bin storage of larger samples. Room for a junk pile.

General. The most desirable arrangement is a separate building with railroad spur for delivery of heavy machinery and ore samples, and river or storm-sewer connection or the like for disposal of finely ground waste. The spur track should preferably approach the building at a sufficient elevation to permit gravity unloading of bulk-ore samples into a receiving bin, and the unloading platform should be served by a crane that serves the milling room also. The building proper should consist of a large milling room and a number of small rooms for microscopic work, polishing, photographic processing, assaying, flotation testing, screen analysis, shop, small-sample storage, junk pile, etc. The best arrangement for the milling room is a large light room with high roof, preferably having, at one end or side, a strong skeleton framework with three or four floors at 8- to 10-ft.

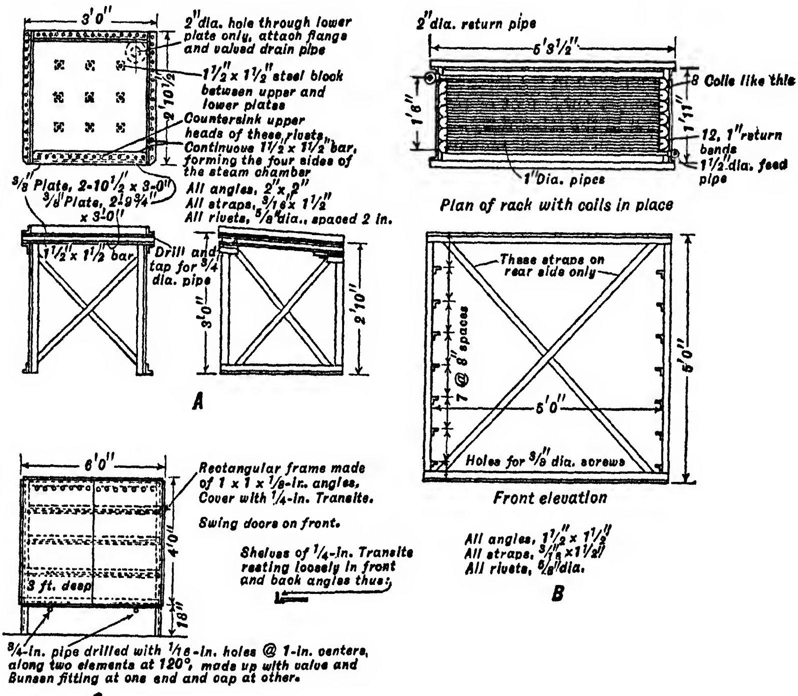

FIG. 164. Laboratory driers.

intervals, stepped back sufficiently to permit ready crane delivery, and a gallery around the rest of the room. The whole room should be crane-served. All but the heaviest apparatus should be set up as a self-contained portable unit, capable of being picked up by the crane and set down in the desired position on the floor or on the skeleton frame for use, and thereafter returned to a place on the gallery for storage. The feed bins should discharge by feeders to a screen, oversize to a jaw crusher, undersize and crusher product to a conveyor and thence to a screen, oversize to a gyratory, undersize and crusher product to a conveyor to a screen, oversize to rolls, undersize and roll product to a bucket elevator to another screen returning oversize to the rolls and undersize to a compartmented fine-ore storage bin. The ideal condition would be to have each of the preceding crushers and screens so placed that it may be picked up and set down in the main milling room for individual test, but if this is not possible the arrangement must be such that each crusher is capable of individual test for capacity, power consumption and size of feed and product. There should be a bucket elevator in the main milling room delivering to the top of the skeleton frame and a battery of centrifugal pumps piped to deliver to any desired level of this frame. The fine-ore storage bins should be arranged for delivery to the elevator boot or to a rod or ball mill and the latter should, of course, be arranged for closed-circuit grinding, if in permanent locations, with finished product going to one of the centrifugal pumps. Set-ups for substantially any concentration or hydrometallurgical process with

gravity flow of pulp can be made on the skeleton framework. This framework should be floored with removable slatted wooden sections about 2 ft. wide by 5 ft. long built up of 2×4-in. yellow pine. A dust-collecting system with suitable inlets at each permanent dry-crushing or screening location and a service line into which temporary inlets may be connected is desirable although not essential. There should be a large sump in the floor of the main room, toward which the floor drains from all directions, with sufficient capacity to hold all excess water from a 1- or 2-hr. concentrating run involving wet screening, hydraulic classification, jigging, and tabling. The sump should discharge to waste by gravity either from bottom outlets or by decantation. A centrifugal pump should be provided to return water from the sump to the water-feed tank. This should be a tank about 6-ft. diameter by 6 ft. deep, located at the highest point of the laboratory, fed by the new-water system and by the sump pump, discharged into the laboratory-supply line by an outlet placed about 6 in. above the bottom, and having an overflow pipe of generous dimensions returning to the sump, a 1-in. telltale line returning with the overflow, and a small drain line from the center of a slightly dished bottom. The water line from this supply tank should be of 3- or 4-in. diameter running around the walls of the laboratory, with permanent branch lines at strategic points and numerous plugged tees and valved outlets, a part of which should be fitted with $^3/_4$-in. and others with 1 $^1/_2$-in. male hose bibbs. There should be a half dozen or more portable cylindrical tanks, 6- and 8-ft. diameter by 2 ft. high, of heavy galvanized-iron sheet, fitted with several 1 $^1/_2$-in. outlets through floor flanges at one place on the rim and one such opening on the wall at the bottom. These are useful for collecting and dewatering sand products, or for holding dewatered slimes, and to keep solid matter out of the sump.

Cleaning up. All apparatus should be capable of complete and ready clean-up. Detail of the necessary arrangement to secure this end will vary with different apparatus, but in general all tanks and hoppers should have sloping bottoms where possible, all machines should be so placed that the material left-in-process can be washed or brushed into receptacles set under them, and all apparatus should be so designed that the amount of material left therein at the end of the run is a minimum.

23. TESTING FOR AMALGAMATION AND CYANIDATION

Amalgamation. Testing for amenability of a gold ore to amalgamation consists in determining the conditions which prevent free clean-gold particles from coming into contact with a clean mercury surface, since such contact invariably results in seizure of the particle by the mercury phase. Testing therefore should be directed toward overcoming the effect of the adverse conditions (Sec. 14, Art. 6).

Mortar-amalgamation test is made by grinding a <35-m. sample in an iron mortar for some definite length of time, after the addition of mercury (about 300 lb. per ton of ore) and the necessary reagents (Sec. 14, Art. 6); pulp densities of 60 to 80% are usual. At the end of the grind, mercury is removed by panning and the tailing is assayed for Au. Tailing should be examined to determine presence of minute mercury globules, due to noncoalescence; additions of caustic soda or ammonium chloride may cause coalescence of such globules with the main mercury body.

Gold pan made of copper, silver-plated copper, or Muntz metal may be surfaced (Sec. 14, Art. 6) with a silver or base amalgam and used to simulate plate amalgamation. A 2- to 5-lb. sample ground fine enough to free precious metals, together with enough water to give a 10 to 25% pulp density, is placed in the pan. The pan is gently shaken for some definite length of time, after which the tailings are recovered and assayed. The charge must not be so large or the size so coarse as to produce scouring of the plate. Reagents such as lime, caustic, acid, etc., may be added as desired. The test may also be made in an unsurfaced pan using a teaspoonful of mercury.

Bottle tests using 40 to 60% pulps, 1% NaOH, and mercury (100 to 150 lb. per ton) are made by placing the charge in a large bottle which is rolled backward and forward for some definite length of time (usually $^1/_2$ to 3 hr.). At the end of the run mercury is recovered by panning.

Tumbling-mill tests simulating barrel amalgamation are made in a small laboratory ball mill (without liners) operated at low speeds. The tumbling media used are small in number and large in size, *e.g.*, 1 piece of shafting or 2 or 3 large balls. Pulp density used depends upon the object of the test; if it is desired to disperse mercury, an 80% pulp density is used; on the other hand a 20 to 40% pulp density is used to keep a mercury pool. Time of test ranges from less than 1 hr. to several hours. Mercury is recovered by panning, and tailing is assayed.

Sizing-sorting-assay tests of the tailing from amalgamation tests (bottle or tumbling-mill tests) yield information concerning liberation and recovery to be expected from finer grinding of sample. *Rose* recommends splitting the sample into size fractions followed by testing of each fraction.

Cyanidation. Amenability is tested by subjecting the ore to limiting conditions prevailing in practice, *e.g.*: Ore, 100 gm. <200-m. Add CaO or NaOH at about 1 : 1 dilution until the pulp remains distinctly alkaline after agitation. Dilute to 25% solids and add cyanide to give 1% KCN solution. Agitate continuously, preferably with free access

of air, for 72 hr. Filter and wash by vacuum. Titrate first filtrate for cyanide. Wash tailing thoroughly with water and assay.

Method of treatment. Determining the probable best method of treatment requires extensive test work. The factors to be investigated are: (*a*) economic grind, (*b*) solution strengths and consumption, (*c*) pulp dilution, (*d*) treatment time, (*e*) necessity for auxiliary treatments and reagents, (*f*) treatment stages. Each of these factors should be varied separately, keeping all other factors constant. In general, most rapid progress will be made by determining first the grind necessary, experimenting at a solution strength indicated by the cyanide consumption in the amenability test. This series of tests can be made to give at least preliminary results on time factor by sampling solutions at, say, 12, 24, 48, and 72 hr. Next, on the basis of these tests, investigate extraction *vs.* solution strength, again making time-factor observations. From this point on the order of tests will vary according to the trend of the preceding results.

Procedure in testing varies according to the nature of the test. Examples follow.

Bottle agitation is employed in most cases. Bottles of 2.5- to 4-li. capacity, with reasonably large mouth to afford some circulation of air, are used for 500-gm. charges; larger or smaller sizes should be used for marked changes in charge weight. They are agitated by placing them on rollers, axis horizontal, at 20 to 30 r.p.m.

Fineness. Grind a batch of ore dry through, say, 20-m. and riffle out a sample (100 to 500 gm.) for test. Grind the balance to 35-m. and cut out a second sample. Repeat at 65-m., 100-m., 150-m., and 200-m. Place the samples with, say, 3 parts of water, in separate bottles; add enough lime to maintain an alkalinity at which ionization of cyanide is reasonably high (see Sec. 12, Art. 10, *Cyanide*), and cyanide to give a solution strength of 0.5% KCN. Agitate 12 hr., withdraw enough solution for assay and for test of alkalinity and cyanide strength; replace solution withdrawn with new solution of a strength to restore the original cyanide concentration and alkalinity. Agitate for another 12 hr. and repeat solution withdrawal and replacement. Do the same at 48- and 72-hr. agitation. Filter, wash, and assay residue.

Solution strength. Prepare six samples at the size indicated best and make up charges with solution strengths of 0.05, 0.10, 0.25, 0.5, 0.75, and 1% KCN, with an amount of lime, as indicated in the fineness test, to maintain suitable *p*H. Agitate for a period which the fineness tests indicated would give reasonably complete extraction. Test final solutions for cyanide and lime, and assay residues. If any of the tests show substantially complete consumption of cyanide, repeat them with replenishment of cyanide, as indicated by titrations, at intervals of a few hours. This may uncover a procedure that will result in as good an extraction as was obtained with stronger solution, with a lower consumption of cyanide.

Similar experimentation, based on the information afforded in each case by all preceding tests, should be used to run down other factors.

Percolation test should be made whenever results of the fineness test show promise in the coarse sizes. Crush a sample to the suspected size, and deslime thoroughly by repeated decantation or by hydraulic classification. Drain as completely as possible. Mix thoroughly by passing through a coarse screen and sample for moisture and assay. Add lime in an amount predetermined by the ore-acidity tests and place in a percolation tank, comprising a container and a suitable sand-tight filter bottom with means for controlled withdrawal of solution from below the filter. Add solution at the top once or twice daily, in amounts of 0.1 to 0.2 times the weight of ore each time. Start with a weak solution to displace moisture, making several additions and immediate withdrawals until solution strength does not change appreciably in passage. Then put on strong solution and let stand for 24 hr. before withdrawal. Follow with several successively weaker solutions, and end with a water wash not exceeding in weight the original moisture introduced. Measure and test all solutions withdrawn for cyanide, alkalinity, and metal content. Finally empty charge, mix, sample, and assay.

Calculations from a test are typified by the following (*RI 3370*). Test procedure involved the steps:

(1) Grind a 250-gm. portion of <20-m. ore with 2.0 gm. of lime (80% available CaO) plus 125 cc. of water in a porcelain pebble mill to about 98% <100-m. and wash the wet pulp to a tared bottle and weigh. (Pulp wgt., 2,050 gm.)

(2) Remove 800 cc. of clear solution, which contains, by titration, 1.1 lb. CaO per ton.

(3) Add 1.0 gm. of c.p. NaCN (2.0 lb. NaCN per ton of solution).

(4) Agitate for 24 hr. on rolls, remove, and allow to settle.

(5) Remove 660 cc. of clear solution by decantation. Titration shows 1.80 lb. NaCN and 0.90 lb. CaO per ton. Take 16 assay-tons for assay. Add 660 cc. of water to bottle, together with 0.4 gm. lime and 0.7 gm. c.p. NaCN.

(6) After 48 hr. total agitation remove from rolls and allow to settle. Analyze clear solution for CaO and NaCN, and assay (16 A.T.). Analysis shows 1.95 lb. NaCN and 0.90 lb. CaO per ton.

(7) Transfer pulp to a suction filter. Wash residue with water to free from dissolved metals, dry, and prepare for assay.

Assays: 24-hr. solution, 0.106 oz. Au, 2.077 oz. Ag; 48-hr. solution, 0.385 oz. Au, 0.752 oz. Ag; residue, 0.025 oz. Au, 0.72 oz. Ag.

COMPUTATIONS:

	Oz. Au per ton		Oz. Ag per ton
24-hr. solution, 660 cc. at	0.106 = 69.96	and	2.077 = 1,370.82
48-hr. solution, 1,000 cc. at	0.0385 = 38.50	and	0.752 = 752.00
Cyanide residue, 250 gr. at	0.025 = 6.25	and	0.72 = 180.00
Calculated head, 250 gr. at	0.459 = 114.71	and	9.21 = 2,302.82

EXTRACTION OF GOLD: 24-hr., 0.106 × 1,000 × 100/114.71 = 92.4%. 48-hr., (69.96 + 38.50)100/114.71 = 94.5%.

EXTRACTION OF SILVER: 24-hr., 2.077 × 1,000 × 100/2,302.82 = 90.2%. 48-hr., (1,370.82 + 752.00)100/2,302.82 = 92.2%.

LIME and CYANIDE CONSUMPTIONS are calculated on a weight-balance basis from the analyses given above. Net consumption of cyanide after regeneration is best estimated on the basis of regeneration performances.

Other tests. A great variety of conditions may occur in different ores, which necessitate an elaborate research into such questions as the necessity or disadvantage of preliminary water-wash, acid-wash, or alkali-wash, oxidizing agents, roasting, concentration, amalgamation, or other process, and the use of additional reagents during cyanide treatment, such as bromocyanide, lead salts, etc. These tests are not, however, in the general class of preliminary tests. Water-washing is advisable for partly oxidized ores containing iron or copper sulphides, and acid-washing is also frequently beneficial under the same conditions, particularly where basic sulphates insoluble in water are present. Alkali washes may be advisable with arsenical and antimonial ores. Oxidizing agents improve extraction from certain ores containing easily oxidizable sulphides and certain kinds of organic matter; preliminary treatment with permanganate, with or without dilute sulphuric acid, is sometimes advantageous when these conditions are present. Roasting is beneficial and sometimes essential with ores containing heavy sulphides, arsenides, sulpharsenides, tellurides, etc., but the cost of operation, in comparison with the possible increased saving of valuable metals, should always be considered. Concentration is often advantageous when values are associated with sulphides or other heavy minerals, provided that the latter do not constitute too large a percentage of the ore. Amalgamation should always be tried in presence of coarse Au and perhaps, also, of native Ag. Bromocyanide has been commercially successful only with telluride and with mispickel ores.

Summary. The tests recited herein are for preliminary purposes only. Before a mill is designed, tests should be made on one or more lots of several tons, in which tests countercurrent slime treatment, agitation, and percolation (if indicated) in tanks of pilot-mill size are tested by an experienced operator.

24. MILLING CALCULATIONS

Computations of performance in milling are complicated by the fact that it is a continuous rather than a batch operation, that the quantities of solid materials handled are large and usually mixed with water, hence difficult or impossible to weigh. Fortunately it is possible to determine many facts concerning performance without knowing weights, if the value of various constituents is known in some common unit, *e.g.*, the content of some particular metal or mineral, or of water, or some ingredient soluble therein, or of particles of a particular size or falling within some particular size range, or the like. Metal content may be expressed in per cent. by weight or volume, or in units of weight as ounces per ton, or even in units of value, as in dollars per ton, provided, in the latter case, that the value is in direct proportion to the metal content and not an artificial value dependent both upon metal content and lack of other content, as is frequently the case in valuation of concentrate.

Balances. The laws of conservation of matter and conservation of energy constitute powerful tools for testing industrial processes, since they supply the bases for the equations:

MATERIAL BALANCE: *Input of material = output of material + loss.*

ENERGY BALANCE: *Input of energy = output of energy + loss.*

Material balance may be applied to the entire mass of material undergoing treatment or to any specific ingredient thereof; in either event, it may be applied to the entire process or to any part thereof. For example, in a dry-crushing plant the total weight of rock material delivered from the quarry into the plant over any period of time must equal the sum of the weights of the crushed products, plus dust losses and spills, plus loss due to evaporation of moisture, if any, provided only that the period taken is long enough to average out any holdups of material in machines, storage bins, and the like. Similarly,

in a copper concentrator the weight of ore delivered to the mill plus the weight of water added at different points in the flow must equal the weight of solids plus solution discharged as concentrate and tailing. If we are interested only in the copper-material balance, the basic equation becomes:

Input of copper in mill feed = output of copper in concentrate + copper in solid tailing + copper in tailing water + copper in dust losses + copper in spills.

If dust and spills go back into one of the regular streams they are omitted from the balance.

Any other ingredient of the treatment stream, *e.g.*, iron, silica, lead, gold, water, etc., may be independently balanced. Similar balances are applicable to smelters, refineries, manufacturing plants, and the like, irrespective of the process in use, be it chemical or physical. In continuous operations the proviso must always be made that the amount of material taken for balance be so large that the percentage amount of material possibly held up shall be less than the permissible percentage error in the balance. Thus, if a 2,000-ton bin, sometimes empty and sometimes full, is located somewhere in the flow that is to be balanced, the amount of material taken for balance should be at least 100,000 tons for a 2% error. On the other hand, if the bin were filled to the same level at the end of the balance as at the beginning, it need not be considered at all, save for minor fluctuations.

Stoichiometric balance is a form of material balance. In the form most frequently used, it is the familiar stoichiometric equation of chemistry, *e.g.*, $CaCO_3 \rightleftharpoons CaO + CO_2$. Applied with qualitative strictness to a flotation cell, it is a strong deterrent to the miracle type of rumination that passed for thought in the early days of the process. No one has yet had the analytical skill to make a complete quantitative application, but each partial application has moved ahead knowledge of the art and skill in its control.

Energy balance is used industrially principally in the form of a heat balance. This has extensive applications in investigations of operations in power plants, smelters, oil refineries, and the like.

Definitions and notation given below obtain throughout all of the calculations.

C = weight of concentrate, expressed in any units, but necessarily in the same units as the feed F. CONCENTRATE may be defined, for the purpose of the calculations, as the product of the treatment of a given feed which has a higher content of a given ingredient than the feed.

$C_1, C_2, C_3 \cdots$ = weights of various concentrates. When a feed contains more than one valuable ingredient, and a concentrate of each ingredient is made, the subscripts refer to such concentrates.

c = assay of concentrate. See notes to f.

$c_{1a}, c_{1b}, c_{2a}, c_{2b}, \cdots$ = assays of the various concentrates relative to the different ingredients. Thus the lead assay of the lead concentrate C_1 would be denoted by c_{1a}, and the zinc assay of the same concentrate by c_{1b}; the lead assay of the zinc concentrate C_2 by c_{2a}, and the zinc assay of the zinc concentrate by c_{2b}. The alphabetical subscripts thus refer to the same ingredient assayed for, throughout a given set of calculations.

F = weight of feed, expressed in any units. FEED is defined as the material entering treatment in any machine or operation, *e.g.*, ore entering a treatment plant, or the material entering a particular machine.

f = assay of feed. As stated in the introductory paragraph, this assay may be given in any units, *e.g.*, % Pb, oz. Au per ton, lb. Cu per ton; dollars per ton, when the value is directly proportional to the weight of a given constituent, say gold or silver, but not when the value is the combined value of the gold and silver, unless the ratio of weight of gold to silver is the same in all products as in the feed; % <1-mm. material, % moisture, % ash (in coal), etc.

$f_a, f_b, f_n, \cdots$ = assay of feed with respect to the ingredients $a, b, c, \cdots$ See note to $c_{1a}, c_{1b}, \cdots$

K = RATIO OF CONCENTRATION. This term is defined as the ratio of the weight of the feed in a given operation to the weight of concentrate obtained from it; or, stated another way, as the number of tons of feed required to produce one ton of concentrate.

$K_a, K_b, K_c, \cdots$ = ratio of concentration with respect to $a, b, c, \cdots$ See note to $c_{1a}, c_{1b}, \cdots$

M = weight of middling, expressed in any unit, but necessarily in the same unit as F. MIDDLING is defined, for the purpose of these calculations, as the product of the treatment of a given feed, with a content of a given ingredient which lies between the content of the tailing and that of the concentrate.

m = assay of middling.

$m_a, m_b, m_c, \cdots$ = assay of middling with respect to ingredients $a, b, c, \cdots$

R = recovery. The terms EXTRACTION, INDICATED EXTRACTION, ESTIMATED EXTRACTION, and ACTUAL EXTRACTION are sometimes used to indicate recovery. The terminology is so confused that the meaning of none of the terms can be safely assumed without indication of the method of determination. Some writers have attempted to distinguish between extraction and recovery, making the former term mean the value of R as calculated from assays of feed and products (see Eqs. 133, 147, 157, and 158) while recovery indicates the ratio of the weight of metal in concentrate actually recovered (= actual weight of concentrate × assay of concentrate) to the actual weight of metal in the feed (= actual weight of feed × assay of feed). Other writers use the term indicated extraction or estimated extraction to signify R from assay alone, and actual extraction to signify the percentage of the total metal fed that is actually recovered in concentrate. In this book the word recovery is used generally to describe the result by either method of calculation and the term ACTUAL RECOVERY to distinguish, when necessary, the case in which calculation is based on actual weights. The words RECOVERY and YIELD are used synonymously. When the feed contains more than one valuable ingredient, it is usual to calculate and express recovery separately for each such ingredient.

$R_a, R_b, R_c, \cdots$ = recoveries of $a, b, c, \cdots$

T = weight of tailing, expressed in any unit, but necessarily in the same unit as F. TAILING is defined, for the purpose of these calculations, as that product of the treatment of a given feed which is distinctly impoverished in content of a given ingredient as compared with the feed.

t = assay of tailing.

$t_a, t_b, t_c, \cdots$ = tailing assay with respect to ingredient $a, b, c, \cdots$

Two-Product Formulas

The simplest case is that in which two products only, *viz.*, concentrate and tailing, are made from the treatment of a given feed. Under such circumstances:

$$\text{Weight balance: } F = C + T \tag{124}$$

$$\text{Ingredient balance: } Ff = Cc + Tt \tag{125}$$

Multiply Eq. 124 by t, eliminate T, and

$$C = F(f - t)/(c - t) \tag{126}$$

$$F = C(c - t)/(f - t) \tag{127}$$

By similar manipulation,

$$T = F(c - f)/(c - t) \tag{128}$$

$$F = T(c - t)/(c - f) \tag{129}$$

$$T = C(c - f)/(f - t) \tag{130}$$

$$C = T(f - t)/(c - f) \tag{131}$$

By definition, $K = F/C$, whence from Eq. 126,

$$K = (c - t)/(f - t) \tag{132}$$

By definition, $R = 100Cc/Ff$, whence from Eq. 126,

$$R = 100c(f - t)/f(c - t) \tag{133}$$

If four of the six quantities, including two of the assays, are known, it is always possible to solve for the unknown two by means of Eqs. 124 and 125.

Three Products, One Metal

When three products are made and assays are reported in terms of one ingredient only, if no weights are known, determinations of recovery and ratio of concentration are strictly indeterminate problems. If enough is known with respect to the performance of the ore to justify an assumption as to the effect of middling retreatment on the assays of final concentrate and tailing, correction of concentrate and tailing assays may be made on the basis of the assumption, and the preceding formulas may then be applied. For an example, see Art. 21 (***Sizing-sorting-assay test***). If the assumption be made that retreatment of middling will result in distribution thereof into concentrate and tailing of the same assays as the corresponding products made in the operation that produced the middling, then if X and Y represent the final weights of concentrate and tailing respectively from the original and retreatment operations

$$C + M + T = X + Y \tag{134}$$

and

$$Cc + Mm + Tt = Xc + Yt \tag{135}$$

Eliminating Y

$$X = [C(c - t) + M(m - t)]/(c - t) \tag{136}$$

and

$$Y = \frac{M(c - m)}{(c - t)} + T = 1 - \frac{C(c - t) + M(m - t)}{c - t} \tag{137}$$

Eqs. 126 and 128 will, however, give the same result.

If two of the weights F, C, M, T are known in addition to the assays, the other weights and the recovery and ratio of concentration may be calculated by manipulation of the two following equations:

$$\text{Weight balance: } F = C + M + T \tag{138}$$

$$\text{Ingredient balance: } Ff = Cc + Mm + Tt \tag{139}$$

Whence

$$C = \frac{F(f - t) - M(m - t)}{(c - t)} = \frac{T(m - t) - F(m - f)}{(c - m)} = \frac{T(f - t) - M(m - f)}{(c - f)} \tag{140}$$

$$M = \frac{F(f - t) - C(c - t)}{(m - t)} = \frac{F(c - f) - T(c - t)}{(c - m)} = \frac{T(f - t) - C(c - f)}{(m - f)} \tag{141}$$

$$F = \frac{C(c-t) + M(m-t)}{(f-t)} = \frac{T(m-t) - C(c-m)}{(m-f)} = \frac{M(c-m) + T(c-t)}{(c-f)} \tag{142}$$

$$T = \frac{C(c-m) + F(m-f)}{(m-t)} = \frac{F(c-f) - M(c-m)}{(c-t)} = \frac{C(c-f) + M(m-f)}{(f-t)} \tag{143}$$

$$c = \frac{f - Mm - Tt}{1 - M - T} \tag{144}$$

$$m = \frac{f - Cc - Tt}{1 - C - T} \tag{145}$$

$$t = \frac{f - Cc - Mm}{1 - C - M} \tag{146}$$

$$R = 100\left[\frac{c(f-t)}{f(c-t)} - \frac{Mc(m-t)}{Ff(c-t)}\right] = 100\left[\frac{c(m-f)}{f(c-m)} - \frac{Tc(m-t)}{Ff(c-m)}\right]$$
$$= 100\left(1 - \frac{Tt}{f}\right) = 100\left[\frac{Cc(f-t) + Mm(f-t)}{Cf(c-t) + Mf(m-t)}\right] \tag{147}$$

$$K = \frac{F(c-t)}{F(f-t) - M(m-t)} = \frac{F(c-m)}{T(m-t) - F(m-f)} = \frac{C(c-t) + M(m-t)}{C(f-t) + M(f-t)} \tag{148}$$

Other equations for K and R may be written by manipulation of Eqs. 138 to 143, but the simpler procedure is to solve for weights of feed and concentrate, after which solutions of K and R are obtainable from the definition equations.

Three-Product Formulas

For 3-product formulas involving one ingredient only, see p. 191. When a feed containing, say, metal a and metal b is so treated as to make three products, *e.g.*, concentrate rich in metal a, another concentrate (or middling) rich in metal b, and a tailing impoverished in both a and b, equations may be written that express the recoveries and ratios of concentration in terms of assays alone, and the weights of the different products in terms of assays and the weight of the feed. Thus

Weight balance: $F = C_1 + C_2 + T$ (149)

Ingredient a balance: $Ff_a = C_1c_{1a} + C_2c_{2a} + Tt_a$ (150)

Ingredient b balance: $Ff_b = C_1c_{1b} + C_2c_{2b} + Tt_b$ (151)

Then from the solution of these simultaneous equations (most readily made by the method of determinants)

$$C_1 = F\left[\frac{(f_a - c_{2a})(c_{2b} - t_b) - (f_b - c_{2b})(c_{2a} - t_a)}{(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)}\right] \tag{152}$$

$$C_2 = F\left[\frac{(c_{1a} - f_a)(f_b - t_b) - (c_{1b} - f_b)(f_a - t_a)}{(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)}\right] \tag{153}$$

$$T = F\left[\frac{(c_{1a} - c_{2a})(c_{2b} - f_b) - (c_{1b} - c_{2b})(c_{2a} - f_a)}{(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)}\right] \tag{154}$$

Ratio of concentration with respect to metal a is, by definition $K_a = F/C_1$. Substituting in this equation the value of C_1 from Eq. 152

$$K_a = \frac{(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)}{(f_a - c_{2a})(c_{2b} - t_b) - (f_b - c_{2b})(c_{2a} - t_a)} \tag{155}$$

Similarly, $K_b = F/C_2$, and from Eq. 153

$$K_b = \frac{(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)}{(c_{1a} - f_a)(f_b - t_b) - (c_{1b} - f_b)(f_a - t_a)} \tag{156}$$

Recovery of metal a in C_1 is given by the equation $R_a = 100(C_1c_{1a}/Ff_a)$. Substituting in this equation the value of C_1 from Eq. 152

$$R_a = \frac{100c_{1a}[(f_a - c_{2a})(c_{2b} - t_b) - (f_b - c_{2b})(c_{2a} - t_a)]}{f_a[(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)]} \tag{157}$$

Similarly, $R_b = 100C_2c_{2b}/Ff_b$ and from Eq. 153

$$R_b = \frac{100c_{2b}[(c_{1a} - f_a)(f_b - t_b) - (c_{1b} - f_b)(f_a - t_a)]}{f_b[(c_{1a} - c_{2a})(c_{2b} - t_b) - (c_{1b} - c_{2b})(c_{2a} - t_a)]} \tag{158}$$

Instead of working from the formulas, the weights of the products may be solved for by writing Eqs. 149, 150, and 151 with the assay values written in and solved directly by determinants.

Example. A lead-zinc ore, containing 7.7% Pb and 11.9% Zn, is treated to produce a lead concentrate assaying 50% Pb and 5% Zn; a zinc concentrate assaying 10% Pb and 50% Zn, and a tailing containing 1 % Pb and 2% Zn.

Weight balance: $F = C_1 + C_2 + T$ (C_1 = Pb conc.; C_2 = Zn conc.)
Lead balance: $7.7F = 50C_1 + 10C_2 + T$
Zinc balance: $11.9F = 5C_1 + 50C_2 + 2T$

Write and solve the determinant for C_1 (see Sec. 21, Art. 4):

$$C_1 = \frac{\begin{vmatrix} 1 & 1 & 1 \\ 7.7 & 10 & 1 \\ 11.9 & 50 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 \\ 50 & 10 & 1 \\ 5 & 50 & 2 \end{vmatrix}} = \frac{\begin{vmatrix} 2.3 & -9 \\ 38.1 & -48 \end{vmatrix}}{\begin{vmatrix} -40 & -9 \\ 45 & -48 \end{vmatrix}} = \frac{232.5}{2{,}325} = 0.10$$

Similarly write and solve the determinant for C_2:

$$C_2 = \frac{\begin{vmatrix} 1 & 1 & 1 \\ 7.7 & 50 & 1 \\ 11.9 & 5 & 2 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 \\ 10 & 50 & 1 \\ 50 & 5 & 2 \end{vmatrix}} = \frac{\begin{vmatrix} 42.3 & -49 \\ -6.9 & -3 \end{vmatrix}}{\begin{vmatrix} 40 & -49 \\ -45 & -3 \end{vmatrix}} = \frac{-465}{-2{,}325} = 0.20$$

Since $F = 1$, $T = 1 - (0.1 + 0.2) = 0.7$

Recovery of lead in lead concentrate, $R_a = \dfrac{0.1 \times 50}{1 \times 7.7} = 64.9\%$

Recovery of zinc in zinc concentrate $= \dfrac{0.2 \times 50}{1 \times 11.9} = 84.1\%$

Ratio of concentration: lead $= F/C_1 = 1/0.1 = 10:1$; zinc $= F/C_2 = 1/0.2 = 5:1$.

n-Product Formulas

When any number of products, n, are made, formulas giving the weights of each in terms of the weight of feed, the recovery, and the ratio of concentration may be written by the method illustrated in the preceding article, and these formulas may be solved provided accurate assays of the feed and all of the products are given in $n - 1$ independent ways. The formulas, however, become so long and involved that it is usually simpler to write the simultaneous equations with the numerical values inserted and solve for the percentage weights by determinants, as illustrated in the preceding paragraph. Thus for four products C_1, C_2, C_3, T the corresponding assays of which, in three metals a, b, c are c_{1a}, c_{1b}, c_{1c}; c_{2a}, c_{2b}, c_{2c}; c_{3a}, c_{3b}, c_{3c}; t_a, t_b, t_c; made from a feed F with assay f_a, f_b, f_c the formula for C_1 is

$$C_1 = F\left[\frac{\begin{gathered}(c_{2c} - t_c)(c_{3a} - f_a)(t_b - c_{3b}) - (t_a - c_{3a})(c_{2c} - t_c)(c_{3b} - f_b) \\ + (c_{3b} - f_b)(t_c - c_{3c})(c_{2a} - t_a) - (c_{3a} - f_a)(t_c - c_{3c})(c_{2b} - t_b) \\ + (t_a - c_{3a})(c_{2b} - t_b)(c_{3c} - f_c) - (t_b - c_{3b})(c_{2a} - t_a)(c_{3c} - f_c)\end{gathered}}{\begin{gathered}(c_{2c} - t_c)(c_{3a} - c_{1a})(t_b - c_{3b}) - (t_a - c_{3a})(c_{2c} - t_c)(c_{3b} - c_{1b}) \\ + (c_{3b} - c_{1b})(t_c - c_{3c})(c_{2a} - t_a) - (c_{3a} - c_{1a})(t_c - c_{3c})(c_{2b} - t_b) \\ + (t_a - c_{3a})(c_{2b} - t_b)(c_{3c} - c_{1c}) - (t_b - c_{3b})(c_{2a} - t_a)(c_{3c} - c_{1c})\end{gathered}}\right] \tag{159}$$

The equations for C_2, C_3, and T may be written from Eq. 159 by symmetry, *e.g.*, to get C_2, substitute in the numerator of Eq. 159 f_a for c_{2a}, f_b for c_{2b}, f_c for c_{2c}, c_{1a} for f_a, c_{1b} for f_b, and c_{1c} for f_c; to get C_3 substitute in the numerator of Eq. 159 c_{1a} for f_a, c_{1b} for f_b, c_{1c} for f_c, f_a for c_{3a}, f_b for c_{3b}, and f_c for c_{3c}; to get T substitute in the numerator of Eq. 159 f_a for t_a, f_b for t_b; f_c for t_c, c_{1a} for f_a, c_{1b} for f_b and c_{1c} for f_c.

Example of the use of determinants for a 4-product problem follows: Given assays as in Table 71, write the equations in the following form:

Table 71. Specimen assays for 4-product determinant solution

	Pb, %	Zn, %	Cu, %
Feed.........	7.1	5.7	2.26
Lead conc.....	60	1	1
Zinc conc.....	1	40	1
Copper conc...	2	2	10
Tailing.......	1	2	0.1

	Feed		Lead conc.	Zinc conc.	Copper conc.	Tailing
Weight balance:	F	=	$C_1 +$	$C_2 +$	$C_3 +$	T
Lead balance:	$7.1F$	=	$60C_1 +$	$C_2 +$	$2C_3 +$	T
Zinc balance:	$5.7F$	=	$C_1 +$	$40C_2 +$	$2C_3 +$	$2T$
Copper balance:	$2.26F$	=	$C_1 +$	$C_2 +$	$10C_3 +$	$0.1T$

Then

$$C_1 = \frac{\begin{vmatrix} 1 & 1 & 1 & 1 \\ 7.1 & 1 & 2 & 1 \\ 5.7 & 40 & 2 & 2 \\ 2.26 & 1 & 10 & 0.1 \end{vmatrix}}{\begin{vmatrix} 1 & 1 & 1 & 1 \\ 60 & 1 & 2 & 1 \\ 1 & 40 & 2 & 2 \\ 1 & 1 & 10 & 0.1 \end{vmatrix}} = \frac{\begin{vmatrix} -6.1 & 1 & -1 \\ 34.3 & -38 & 0 \\ -1.26 & 9 & -9.9 \end{vmatrix}}{\begin{vmatrix} -59 & 1 & -1 \\ 39 & -38 & 0 \\ 0 & 9 & -9.9 \end{vmatrix}} = \frac{\begin{vmatrix} 197.5 & -38 \\ -53.64 & -0.9 \end{vmatrix}}{\begin{vmatrix} 2203 & -38 \\ -531 & -0.9 \end{vmatrix}} = \frac{2216.07}{22160.7} = 0.10$$

Similarly $C_2 = 0.10$, $C_3 = 0.20$, and $T = 0.60$. From these values the recovery of each metal in its respective concentrate and the respective ratios of concentration may be written.

Limitations of multiproduct formulas. The formulas above given are theoretically correct, but the accuracy of the answers that they give is, of course, wholly dependent upon the accuracy of the sampling and assaying. The formulas for two-product treatment are not particularly sensitive to small errors in data or calculation, hence recovery and weight of concentrate should check smelter returns (or their equivalent). If they do not check, mill operation should be examined for spills, losses, hold-backs as in tanks, etc., and shipping and smelter sampling should be carefully scrutinized.

The formulas for three or more products are more sensitive to small errors both in data and calculation, especially when one of the products is of relatively small weight and low assay.

Fry (*114 J 493*) cites an example of the effect of such errors. His actual assays and assumed erroneous assays together with weights of products calculated from both by determinants, using the four possible equations three at a time, are shown in Table 72. The calculated weight of feed in the columns whose heading contains the letter W (which indicates that one of the simultaneous equations was $F = L + Z + T$) should, of course, be 100.0. The difference is due to slide-rule discrepancies, which, in some cases, may become very important. The difference between the calculated weight and 100 in the last column measures the effect of both assays and slide rule. It will be noted that the errors that Fry assumed made but little difference in calculated weights in the case where the silver assay was not used, but that impossible results were obtained when the erroneous silver assays were included in the calculation.

Table 72. Possible effect of small errors in assaying and sampling on calculated weights in 3-product concentration (*Assays from Fry, 114 J 493*)

	Pb, %	Zn, %	Ag, oz. per ton	Calculated weights, %			
				Data used *a*			
				WLZ	WLS	WZS	LZS
Actual assays:							
Feed	11.34	31.85	13.2	100.69	100.4	100.0	102.84

a W weight equation. L Lead equation. Z Zinc equation. S Silver equation.

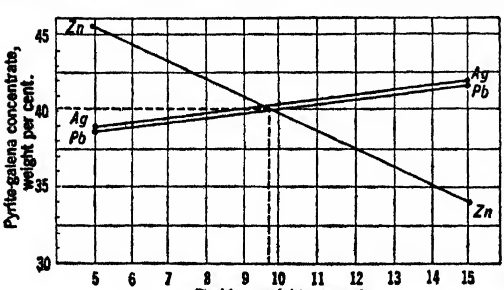

FIG. 165. Graphical solution of three-product problem.

Graphical solution. Fig. 165 shows a method, proposed by Fry, for a graphical solution designed to point out inaccuracies in sampling and assaying and at the same time average them, if they are not too large to be averaged. The chart is constructed as follows: Assume two values for the weight of tailing T, one less than the probable, the other more. Using these assumed values, *e.g.*, in the case of the erroneous assays given, 5 and 15%, write equations in L (weight of lead concentrate) as follows:

Using the zinc assays

$$31.8\,(100) = 9L + 56\,(95 - L) + (5)\,(1), \text{ from which } L = 45.6$$
$$31.8\,(100) = 9L + 56\,(85 - L) + (15)\,(1), \text{ from which } L = 33.9$$

Using the lead assays

$$11.3\,(100) = 21.3L + 5.4\,(95 - L) + 5\,(0.7) \text{ from which } L = 38.6$$
$$11.3\,(100) = 21.3L + 5.4\,(85 - L) + 15\,(0.7) \text{ from which } L = 41.6$$

Using the silver assays

$$13.3\,(100) = 25L + 6.3\,(95 - L) + 5\,(0.7) \text{ from which } L = 38.9$$
$$13.3\,(100) = 25L + 6.3\,(85 - L) + 15\,(0.7) \text{ from which } L = 41.9.$$

Plot the assumed values of T as abscissae and the derived weights of L as ordinates and connect the corresponding values with straight lines. Read the mean of the two intersections as mean values of L and T. In this case L was read off as 40.1 and T as 9.65, which gave Z (weight of zinc concentrate) 50.25 by difference.

Applications of Formulas

The most usual applications of the formulas are to control the operations of individual machines and of the whole mill and to check smelter returns. If feed is weighed in automatically and accurate moisture determinations are made, the calculated weight of concentrate over a period such as a month should check dry weight of concentrate shipped within reasonably close limits, and over a period of a year should check very closely. Discrepancy in one direction only should be closely investigated; differences should be both positive and negative over a period of time.

In mills where the feed is not weighed, tailing should be time-sampled. Weights of concentrate and tailing may then be calculated and the former weight checked against the shipping weight.

As indicated in the introductory paragraph, the two-product formulas may be applied to investigations of the performance of screens and two-product classifiers. (See also Sec. 7, Art. 2.) In these cases the assays are usually screen analyses. The size split for statement of assays should be a screen that gives 5%, or more if possible, as the minimum assay used. Ordinarily cumulative percentages on or through the key screen are chosen as the assays rather than individual percentages. For another formula for investigating classifier performance, see Eq. 164.

In laboratory testing three products are usually made, *viz.*, concentrate, middling and tailing. As discussed at p. 191, some assumption must be made with respect to middling distribution, if the two-product formulas are to apply. In flotation testing it is ordinarily justifiable to assume that retreatment of middling would not affect primary concentrate or tailing assays, but the same assumption cannot ordinarily be made in gravity concentration.

Efficiency of concentration. It is apparent from inspection of the two-product formulas for recovery and ratio of concentration that if all of the feed was merely shoveled to one side and called concentrate, the recovery would be 100%. The ratio of concentration would be 1, which would, of course, tell what had been done. This shows that recovery and ratio of concentration, or, at least, assay of concentrate, must be stated together in order that the figures may give a measure of the efficiency of the concentrating operation. Several proposals have been made to combine the numerical values of recovery and ratio of concentration, or ratio of assay of concentrate to assay of feed or tailing into one number called an efficiency index. No proposal, however, shows a logical method of combination or one that has a physical significance that can be visualized. Hence it is better to give the two numbers, as is usual.

Evaluation of flotation tests either by definition of an index of efficiency or by correlation of recovery and ratio of concentration or product composition has been the subject of a considerable amount of work.

Selectivity index. Gaudin (*87 A 483*) defined a selectivity index as the geometric mean of the relative floatability and the relative rejectability. Relative floatability is relative recoverability. For a binary ore $R_a = Cc_a/Ff_a$, and $R_b = Cc_b/Ff_b$ but $c_b = 100 - c_a$, and $f_b = 100 - f_a$. Whence

$$\frac{R_a}{R_b} = \frac{c_a(100 - f_a)}{f_a(100 - c_a)} = \frac{f_b(100 - c_b)}{c_b(100 - f_b)} \tag{160}$$

Relative rejectability is relative recoverability in the tailing, *i.e.*, $R(T)_a = Tt_a/Ff_a$, and $R(T)_b = Tt_b/Ff_b$; $t_b = 100 - t_a$. Whence

$$\frac{R(T)_b}{R(T)_a} = \frac{t_b(100 - f_b)}{f_b(100 - t_b)} = \frac{f_a(100 - t_a)}{t_a(100 - f_a)} \tag{161}$$

The selectivity index S is

$$S = \left[\frac{R_a}{R_b} \times \frac{R(T)_b}{R(T)_a}\right]^{1/2}$$

$$S = \sqrt{c_a t_b / c_b t_a} \tag{162}$$

As was noted previously, there is no *a priori* logical foundation for this index, hence interpretation depends upon comparison with accumulated data of performance.

Graphical evaluation. Gillies *et al.* (*A TP 1409*) devised a graphical method for evaluation of flotation tests. Its use involves a minor change in testing procedure; a series of concentrates are removed instead of a single concentrate. These concentrates are assayed and cumulative recoveries calculated. Per cent. cumulative rejections of gangue are also calculated. The sum of the per cent. recovery and the per cent. rejection of gangue minerals is calculated for each fraction; the result is called the SUMMATION INDEX. Fig. 166 shows a plot of these indices. The summation-index curve shows a maximum at about the point where the recovery of the values is almost complete. This maximum is claimed to indicate "best" results. But best results differ according to the criterion. If, as is usually the case, this is net return per ton of feed, the method does not apply, since return per unit of concentrate varies with the grade.

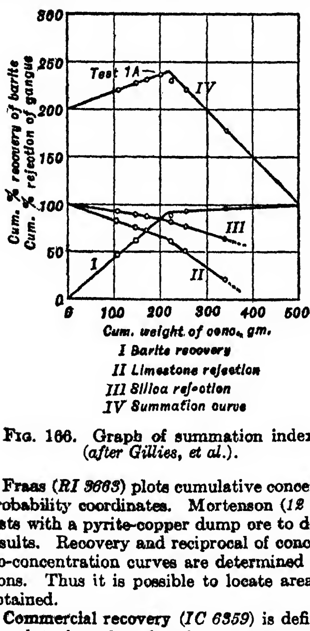

FIG. 166. Graph of summation index (*after Gillies, et al.*).

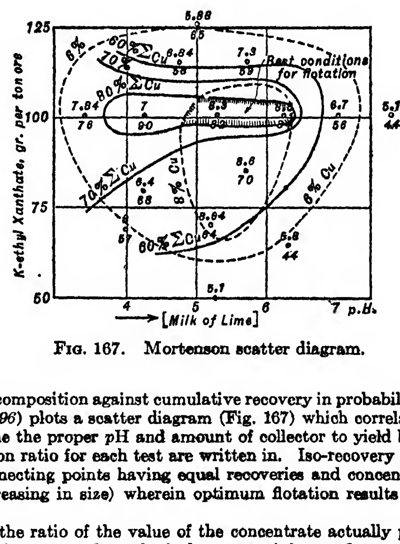

FIG. 167. Mortenson scatter diagram.

Fraas (*RI 3663*) plots cumulative concentrate composition against cumulative recovery in probability-probability coordinates. Mortenson (*12 MMt 496*) plots a scatter diagram (Fig. 167) which correlates tests with a pyrite-copper dump ore to determine the proper pH and amount of collector to yield best results. Recovery and reciprocal of concentration ratio for each test are written in. Iso-recovery and iso-concentration curves are determined by connecting points having equal recoveries and concentrations. Thus it is possible to locate areas (decreasing in size) wherein optimum flotation results are obtained.

Commercial recovery (*IC 6359*) is defined as the ratio of the value of the concentrate actually produced to the value of perfect concentrate (resulting from a hypothetical process giving perfect recovery and perfect separation). Assays of the perfect concentrate are assumed after proper consideration of the mineralogical composition of the ore. At the BLACK HAWK concentrator perfect zinc concentrates are assumed to contain 56% zinc. Perfect lead concentrates vary with the copper content of the ore; when the plant is working on a so-called combination ore, perfect lead concentrate is assumed

Table 73. Metallurgical results at Black Hawk

to assay 50% Pb. The ratio of concentration, $K_{\text{perf.}}$, for perfect Pb concentrate and perfect recovery equals the ratio of Pb in perfect concentrate to Pb in ore. The assays for Ag and Cu in the perfect Pb concentrate are the products of $K_{\text{perf.}}$ and the respective assays for these metals in the ore. Evaluation of these products is obtained by applying the current metal quotations to the smelter contract in force, making deductions for freight and treatment charges. Table 73 gives metallurgical results, and Table 74, commercial recovery for a monthly period at BLACK HAWK.

b Recovery: 1,691.88/2,085.45.

At BUNKER HILL & SULLIVAN (*IC 6314*) concentrator efficiency is estimated by the ratio of the net smelter value of the products to the gross market value of mill feed, using the same price quotations in both cases. This ratio is called the economic extraction. Fig. 168 gives the relationship existing between economic extraction and recovery and grade, in a hypothetical case. Economic recoveries based on total Ag, Pb, and Zn range from 40 to 80%. A similar measure of efficiency was used at the Pecos concentrator of the AMERICAN METAL Co. (*IC 6605*). The economic extraction at Pecos for 1930 (based on 1927 metal prices, freight, and treatment costs) was 52.9% for the lead circuit, 37.1% for the zinc circuit, and 43.3% based on the total circuit.

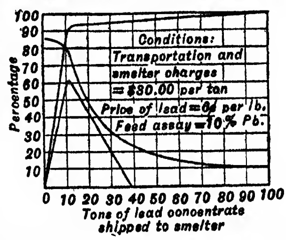

FIG. 168. Graph illustrating economic extraction.

Evaluation of concentration performance. In judging different performances in a given mill or comparing performances in different mills superiority is not established by simple comparison of recoveries and/or grades of concentrate or by any of the attempted one-number combinations of these measures (*vide: Selectivity index; Summation index*), but rather by the monetary returns, which constitute the practical integrated measure of the utility of the operation. For ores that yield one product only, the net return per ton of feed is the net value of a ton of product, *e.g.*, metalliferous concentrate, divided by the ratio of concentration. This net value is, of course, gross return per ton of concentrate less smelter charge, freight, and milling cost. When two or more products are made, comprising an equal or greater number of value-producing constituents (*e.g.*, a lead-copper concentrate containing gold and silver and a zinc concentrate containing appreciable amounts of gold), although the principle of analysis is the same, the application is much more complicated.

Freeman (*81 Aa 9*) describes a method of analysis for such a case for use in a given mill, which comprises setting up, once for all, a series of tables showing the effects on net returns of the various performance variables throughout their normal range of variability, whereupon any given performance record can be compared readily either with a standard performance or with any other specific performance in such a way as to show which particular element or elements of difference preponderate in the over-all difference calculated.

Example. Freeman gave as an example a lead-zinc-silver ore for which the data in Table 75 constituted standard conditions. By application of the metal prices, and the smelter and freight schedules then prevailing, he calculated the revenue per ton of ore for the standard ore and concentrating performance to be: from lead, $5.03; from silver, $0.95; from zinc, $0.29; total, $6.27. By further application of metal prices, smelter, and freight schedules, he set up Tables 76 to 82. Application of these tables to any set of conditions within their range is illustrated in Tables 83 and 84. Case A shows a profit of 6.88¢ per ton above standard, Case B is 66.88¢ above standard, or 60¢ per ton of feed superior to Case A. Examination of details shows, however, that practically all of the advantage of Case B above standard is due to the higher lead and silver assays of the feed, whereas in Case A the small advantage over standard is due to better technology as regards zinc and silver, which overbalances the slump in lead results. Hence from a metallurgical standpoint Case A is better than Case B.

Table 75. Analysis of standard ore (*after Freeman*)

Classifier Formulas

Efficiency. Eq. 133 may be, and ordinarily is, used, together with Eq. 132, to give an idea of the relative amounts of sand discharge and overflow. CLASSIFIER EFFICIENCY has been defined as the ratio, expressed as percentage, of the weight of classified material in the overflow to the weight of classifiable material in the feed. Overflow having the same sizing test as the feed is not said to be "classified material." Thus, if the separating size were 35-m. and 100 tons of classifier feed contained 50% of <35-m. material while the 50 tons of classifier overflow contained 90% <35-m., the 5 tons of >35-m. in the overflow plus 5 tons of <35-m. would comprise 10 tons of overflow of the same size composition as the feed. The net classified material in the overflow would, then, be 40 tons, and efficiency, $E = 100 \times 40/50 = 80\%$. This can be expressed in terms of size assays alone as follows: Let $100 - f = \%$ of oversize in feed, and $100 - c = \%$ of oversize in overflow. Then actual weight of oversize in overflow $= (100 - c)C/100$, and

$$E = \frac{C - \dfrac{(100 - c)C}{100 - f}}{\dfrac{fF}{100}} \times 100 = 10{,}000\,\frac{C}{F} \cdot \frac{(c - f)}{f(100 - f)} \tag{163}$$

But $C/F = (f - t)/(c - t)$. Substituting this value for C/F in Eq. 163

$$E = \frac{10{,}000(c - f)(f - t)}{f(100 - f)(c - t)} \tag{164}$$

In the example in the preceding text $c = 90$, $t = 10$, and $f = 50$, whence $E = 80\%$. If the finished product contains only desired material, *i.e.*, $c = 100$, this equation becomes the same as the two-product recovery formula (Eq. 133).

If this formula is used for concentrating operations, assays should be expressed as percentages of valuable mineral rather than as percentages of metal, otherwise the operation is penalised (*i.e.*, efficiency is low) because it does not separate metal from the chemically combined elements.

Classifier-screen assay was proposed by Fahrenwald (*87 A 82*) in place of the usual screen assay as a basis for estimating efficiency of a two-product (*e.g.*, desliming) classifier, on the score that sizing assays taken alone penalize the two-product classifier when the feed comprises grains of different shapes and specific gravities. The method of assay consists in making separate multiproduct (*e.g.*, 12-spigot) classifier runs on the feed and each of the products of the two-product classifier, making a sizing test of each of the multiproduct (assay) classifier products, and then plotting, for each of the two-product classifier samples, the weight percentage of overflow of the assay classifier progressively cumulated for each successively coarser product (abscissae in Fig. 169) against the corresponding per cent. undersize of the nominal mesh of separation in each of the assay-classifier products taken separately. Such curves show characteristic breaks A–B (Fig. 169). The abscissa of the upper inflection point A of the smoothed curve is taken as the assay. These values for respective two-product classifier samples should be inserted in the recovery formula (Eq. 133) to determine efficiency.

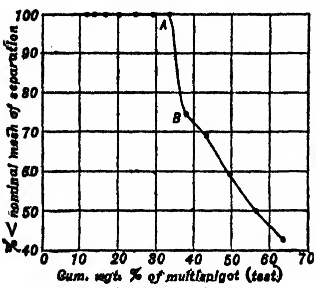

FIG. 169. Fahrenwald classifier-screen assay curve.

The method is laborious. It gives higher efficiency ratings in some cases, probably in all, than the screening assay. Whether the numbers are more significant of relative mill utilities is not apparent.

Efficiency of screens. Usual method of determination is to apply Eq. 133; Eq. 164 may also be used. See also Sec. 7, Art. 2.

Separating and blending formulas. The two-product formulas (Eqs. 124 to 133) are applicable to solution of the problems that arise in separating and blending products by size. Thus let F designate weight of feed (either in units of weight or in percentage), C = weight of the product derived from F by taking away a part of F having the weight D, and having a limiting size smaller than the limiting size of F. Then

$$F = C + D \tag{165}$$

Let B = the blend resulting from adding to F a weight A of a material having a limiting size smaller than the limiting size of F. Then

$$B = F + A \tag{166}$$

Let s = decimal fraction of F that must be taken away to produce a desired residue C, and let i = decimal fraction of F that must be added to make a desired blend B. Then

$$s = D/F \tag{167}$$

and

$$i = A/F \tag{168}$$

Let a, b, c, d, and f denote the cumulative percentages passing any screen denoted by subscript n in the products A, B, C, D, and F respectively. Then

$$Ff_n = Cc_n + Dd_n \tag{169}$$

and

$$Bb_n = Ff_n + Aa_n \tag{170}$$

Multiplying Eq. 165 by c_n, subtracting the resulting equation from Eq. 169, and solving for D/F gives

$$D/F = (f_n - c_n)/(d_n - c_n) = s \tag{171}$$

Similarly, multiplying Eq 166 by b_n, subtracting from Eq. 170, and solving for A/F gives

$$A/F = (b_n - f_n)/(a_n - b_n) = i \tag{172}$$

Substituting for C in Eq. 169 its value from Eq. 165, dividing through by F, substituting s for D/F in the resulting equation, and solving for c_n gives

$$c_n = (f_n - sd_n)/(1 - s) \tag{173}$$

Similarly substituting for B in Eq. 170 its value from Eq. 166, dividing through by F, substituting i for A/F in the resulting equation, and solving for b_n gives

$$b_n = (f_n + ia_n)/(1 + i) \tag{174}$$

If the added material in blending is coarser than F, transpose a_n and f_n in Eqs. 172 and 174; similarly if the subtracted material is removed by a scalping screen, transpose c_n and d_n in Eqs. 171 and 173.

Tonnages in Milling Circuits

Tonnages may frequently be determined by application of the two-product formulas 132 and 133. Fig. 170 shows four typical closed crushing circuits.

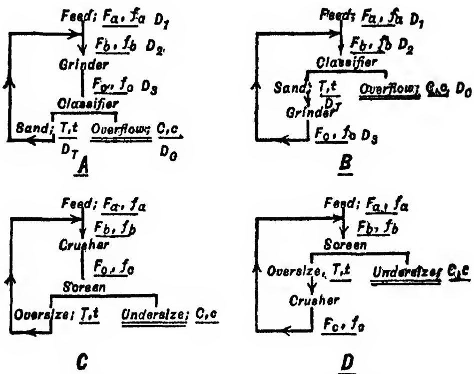

Fig. 170. Typical closed crushing circuits.

In Fig. 170, item A: $K = F_c/C = (c - t)/(f_c - t)$ from Eq. 132. But $C = F_a$. Hence, $F_c = F_a(c - t)/(f_c - t) = F_b$. And

$$T = F_c - C = \frac{F_a(c - t)}{(f_c - t)} - F_a = \frac{F_a(c - f_c)}{(f_c - t)} \tag{175}$$

Also

$$f_b = (F_a f_a + Tt)/(F_a + T) \tag{176}$$

In Fig. 170, item B: $K = F_b/C = (c - t)/(f_b - t)$ from Eq. 132. But $C = F_a$, hence $F_b = F_a(c - t)/(f_b - t)$; and

$$T = F_c = F_b - C = F_b - \frac{F_b(f_b - t)}{c - t} = \frac{F_b(c - f_b)}{c - t} \tag{177}$$

$$f_b = (F_a f_a + F_c f_c)/(F_a + F_c) \tag{178}$$

$$F_c = F_a(f_a - f_b)/(f_b - f_c) \tag{179}$$

From inspection of the figure, $F_a f_a + F_c f_c = Tt + Cc$. But $F_c = T$ and $F_a = C$, hence $T(f_c - t) = F_a(c - f_a)$, and $T = F_a(c - f_a)/(f_c - t)$.

Adding C to both sides of the preceding equation, $T + C = F_a(c - f_a)/(f_c - t) + C$. But $T + C = F_b$ and $C = F_a$,

hence
$$F_b = F_a\left(\frac{c - f_a}{f_c - t} + 1\right) \tag{180}$$

By inspection of Fig. 170, item B: $F_b f_b = F_a f_a + F_c f_c$.

$$f_b = \frac{F_a f_a + F_c f_c}{F_b} = \frac{F_a f_a + \dfrac{F_a(c - f_a)f_c}{(f_c - t)}}{F_a\left(\dfrac{c - f_a}{f_c - t} + 1\right)} = \frac{cf_c - tf_a}{c - f_a + f_c - t} \tag{181}$$

$$f_c = \frac{F_a(c - f_a - t) + F_b t}{F_b - F_a} \tag{182}$$

$$f_a = \frac{f_c(f_b - c) + f_b(c - t)}{f_b - t} = c + (f_c - t)[1 - (F_b/F_a)] \tag{183}$$

By Eq. 133 the value of R in Fig. 170, item B, is

$$R = c(f_b - t)/f_b(c - t) \tag{184}$$

Substituting in this equation the value of f_b,

$$R = \frac{c(f_c - t)}{cf_c - tf_a} \tag{185}$$

Calculations for the cases shown in Fig. 170, items C and D are identical with those for A and B respectively.

Circulating loads (CL) in closed circuits may be estimated in a number of ways.

By size analyses. For Fig. 170, items A and B, above,

Item A: $$\% \; CL = 100T/F_a = 100\,(c - f_c)/(f_c - t) \tag{186}$$

Item B: $$\% \; CL = 100T/F_a = 100F_c/F_a = 100(f_a - f_b)/(f_b - f_c) = 100(c - f_a)/(f_c - t) \tag{187}$$

By means of the identities given above, the circulating load may be written in such form as will utilize the data at hand.

By dilutions. If dilutions or specific gravity of pulps (from which dilutions may be calculated) are known, then per cent. circulating load may be calculated as follows:

Item A: $F_cD_3 = CD_c + TD_t$ (water balance). But since $F_c = F_a + T$ and $C = F_a$, $(F_a + T)D_3 = F_aD_c + TD_t$; whence $(1 + T/F_a)D_3 = D_c + (T/F_a)D_t$, and

$$\% \; CL = 100T/F_a = 100\,(D_c - D_3)/(D_3 - D_t) \tag{188}$$

Item B: $F_aD_1 + F_cD_3 = F_bD_2$ (water balance) $= (F_a + F_c)D_2$; whence $D_1 + D_3(F_c/F_a) = D_2 + D_2(F_c/F_a)$, and

$$\% \; CL = 100F_c/F_a = (D_2 - D_1)/(D_3 - D_2) \tag{189}$$

Tonnage of circulating load. If the actual circulating tonnage is required, the weight of feed or classifier overflow must be known. When the assay formulas are used and screen analyses constitute the assay it is wise to calculate the per cent. circulating load for more than one size and use the average figure; in taking the average, reject all computed circulating loads that are obviously out of line, probably on account of errors in sampling or sieve analysis.

By return tonnage. Determine from the sizing tests of feed and product, the decimal fraction r of the original feed weight F_0 requiring crushing (*i.e.*, with fines eliminated) that failed to be reduced in a single pass. By application of the formula for the sum of a geometric series (Sec. 21, Art. 7), circulating load

$$CL = F_0/(1 - r) \tag{190}$$

Thus if 100 tons per day feed to a set of rolls contained 30 tons undersize of the limiting screen, $F_0 = 70$, and if the product of a single pass showed 65 tons undersize, $r = 35/70 = 0.5$, and S (total feed to the rolls per 24 hr.) $= 30 + 70/(1 - 0.5) = 170$. If the screen returns some undersize with the oversize, r must be increased accordingly.

Dilution method may be employed in the determination of the tonnage in a pulp stream, which, for one reason or another, cannot be adequately time-sampled. Measure the specific gravity, at the point of interest, before and after the addition of a known volume of water. If D_1 and D_2 denote dilutions before and after, and V denotes the volume of water added, then (by water balance) $FD_1 + V = FD_2$ whence tonnage in circuit

$$F = V/(D_2 - D_1) \tag{191}$$

A variant of this method is used at Ohio Copper Co. to determine tailing tonnage. A known volume V of zinc sulphate solution of known concentration is added to the mill tailing pulp at some regular rate. The pulp is sampled downstream, and the sample titrated for zinc. If D_1 = dilution of $ZnSO_4$ added, D_2 = dilution of $ZnSO_4$ in sample, D_3 = dilution of pulp, then tonnage of pulp

$$F = \frac{V}{D_3}\left(\frac{D_2}{D_1} - 1\right) \tag{192}$$

Cyanidation

Tonnage and recovery calculations follow method outlined above, and involve no new method or principles.

Let F weight of feed $= 1$; C = weight of concentrate (if made), T = weight of tailing from concentrating operation ($= F$, if no concentrate is made), A = weight of sand feed, B = weight of slime feed, X = weight of sand tailing, and Y = weight of slime tailing, all expressed as decimal parts of F; and f, c, t, a, b, x, and y = respective assays of the above products.

Then $F = C + T$; $T = A + B$; $f = cC + tT$; $Tt = aA + bB$; $Tt = f - cC$. But $T = F - C = 1 - C$. Hence $(1 - C)t = f - cC$ and

$$C = (f - t)/(c - t) \tag{193}$$

Similarly
$$T = (c - f)/(c - t) \tag{194}$$

$Aa = Tt - Bb$. But $B = T - A$, hence $Aa = Tt - (T - A)b$, and $A/T = (t - b)/(a - b)$. Substitute value of T from Eq. 194, then

$$A = \frac{(c - f)(t - b)}{(c - t)(a - b)} \tag{195}$$

$$B = T - A = \frac{c - f}{c - t} - \frac{(c - f)(t - b)}{(c - t)(a - b)} = \frac{(c - f)(t - a)}{(c - t)(b - a)} \tag{196}$$

$R = [Cc + (Aa - Xx) + (Bb - Yy)]/Ff$. But $F = 1$, and for all practical purposes, $A = X$ and $B = Y$. Hence, substituting A for X and B for Y and then substituting for C, A, and B their equivalents in terms of assays above given, and clearing

$$R = \frac{c(f - t) + \dfrac{c - f}{a - b}[(t - b)(a - x) - (t - a)(b - y)]}{f(c - t)} \tag{197}$$

Formulas Involving Sorting, Roughing, Etc.

The following formulas are useful to determine the monetary saving to be expected from sorting, roughing, or other treatment in which a finished product, either concentrate or tailing, is to be removed in advance of the place that it is removed in the treatment scheme taken as standard.

Removal of concentrate. When the material to be removed is finished concentrate, let H and h = weight in tons and assay respectively of original feed; P and p = weight in tons and assay respectively of the concentrate to be produced by the proposed new operation; M and m = weight in tons and assay respectively of the residue from the proposed new operation; T = tons of final mill tailing without the new operation; T' = tons of final mill tailing to be produced from M tons of residue from the new operation; C = tons of mill concentrate under normal operation; and C' = tons of mill concentrate to be produced from M tons of residue from the new operation; c and t = assay respectively of C, C' and T, T'; V = value in dollars per unit of metal in concentrate to be produced by the new operation; V' = value in dollars per unit of metal in mill concentrate produced by either operation, R = cost of new operation in dollars per ton of concentrate produced thereby (P); S = cost in dollars per ton of milling H tons of original ore; and S' = cost in dollars per ton of milling M tons of residue from the new operation.

The assumption that the assays of tailing and concentrate made from original and sorted ore would be the same is justified by experience to the effect that relatively small changes in the tonnage or assay of mill feed have little effect on the assays of mill products. The values assigned to V and V' should be net and should take full account of penalties, freight, smelting charges, etc.

If the proposed operation is employed, the net return from P tons of concentrate so produced is its value less its cost of production $= PpV - PR$. Return from milling M tons of residue $= C'cV' - MS'$, and total return $= P(pV - R) + C'cV' - MS'$.

If the operation is omitted and the total feed is treated the same as M above, the return $= CcV' - HS$.

The total gain in dollars (or loss, if the sign is negative) to be expected from adoption of the proposed operation is

$$G_T = [P(pV - R) + C'cV' - MS'] - (CcV' - HS)$$

The gain per ton of original feed is

$$G = \frac{P}{H}(pV - R) - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{H}S' + S \tag{198}$$

But $P/H = (h - m)/(p - m)$, from Eq. 132; $C/H = (h - t)/(c - t)$, from Eq. 132; $M/H = (p - h)/(p - m)$ (from the relation $M = H - P$); $C' = M(m - t)/(c - t)$, from Eq. 132. Then

$$\frac{C'}{H} = \frac{M}{H}\left(\frac{m - t}{c - t}\right) = \left(\frac{p - h}{p - m}\right)\left(\frac{m - t}{c - t}\right)$$

whence, by substitution of the above values in Eq. 198

$$G = \frac{(h-m)(pV-R)-(p-h)S'}{p-m} - cV'\left[\frac{h-t}{c-t} - \frac{(p-h)(m-t)}{(p-m)(c-t)}\right] = S \quad (199)$$

Removal of waste. If, instead of concentrate, W tons of waste assaying w is discarded at a cost of R dollars per ton discarded, then when the new operation is employed, the loss due to discarding waste is $= WR$, and the return from milling the remainder $= C'cV' - MS$. Net return $= C'cV' - MS - WR$.

If the proposed operation is omitted, the net return $= CcV' - HS$, whence gain G_T (or loss, if of negative sign) to be expected from installation of the new operation $= C'cV' - MS' - WR - CcV' + HS$, and

$$G = S - cV'\left(\frac{C}{H} - \frac{C'}{H}\right) - \frac{M}{H}S' - \frac{W}{H}R$$

Substituting assay values, as in the preceding development,

$$G = S - \frac{m-h}{m-w}\left[cV'\left(\frac{w-t}{c-t}\right) + R\right] - \frac{h-w}{m-w}S' \quad (200)$$

Saving (or loss) to be expected from cleaning a salable product instead of shipping directly may be obtained by a similar method of analysis.

Let H' = tons of material, h' = assay of H', C' = tons of cleaned product, c' = assay of C', T' = tons of material that will be reject of the cleaning operation, t' = assay of T', R = cost of treatment in dollars per ton of H', V = value, in dollars per unit of metal, of C'; V' = value, in dollars per unit of metal, of H'.

If the material is shipped directly, the return $= H'h'V'$. If cleaning is practiced, the return $= C'c'V - H'R$.

Gain G_T (or loss, if negative) to be expected from the proposed cleaning operation $= (C'c'V - H'R) - H'h'V' = C'c'V - H'(R + h'V')$, whence

$$G = \frac{C'c'V}{H'} - (R + h'V') = \frac{c'V(h'-t')}{c'-t'} - (R + h'V') \quad (201)$$

Saving to be expected by further treatment of a tailing product is the excess value of the concentrate produced by the treatment over the cost of treatment.

If H'' = tons of original tailing, C'' = tons of additional concentrate produced by further treatment of H'', T'' = tons of cleaned tailing, h'', c'', t'' = assays of H'', C'', and T'', respectively, R = cost of treatment per ton of H'', V = value in dollars per unit of metal in the concentrate C''.

Then gain G_T (or loss, if of negative sign) to be expected from the proposed additional treatment $= C''c''V - H''R$, whence

$$G = \frac{C''}{H''}c''V - R = \frac{c''(h''-t'')}{c''-t''}V - R \quad (202)$$

Specific-Gravity Assay

When an ore is a mixture of two minerals only or of one valuable mineral and a mixture of gangue minerals whose relative proportions are substantially constant, it is possible to make rapid approximate assays of a mixture of valuable mineral and gangue by determining the specific gravity of the mixture, provided the individual specific gravities of valuable mineral and gangue are already known. The usual method is by use of a specific-gravity flask.

Weigh the flask empty and when full of water. Dry the flask, introduce the ore sample, weigh; fill with water, taking care to remove all air bubbles, and again weigh. In centimeter-gram units, if S_o = specific gravity of ore, S_m of "mineral" and S_g of gangue; F = weight of dry flask, W = weight of water required to fill the flask, O = weight of dry ore, and T = total weight of flask + ore + water, then the weight of water required to fill the flask, with ore in it $= T - (O + F)$ = volume of water in flask, and volume of ore in flask $= W - [T - (O + F)]$.

$$S_o = \frac{O}{W - [T - (O + F)]} = \frac{O}{F + W + O - T} \quad (203)$$

If m = per cent. of "mineral" in ore = weight of mineral per unit weight of ore; $1 - m$ = per cent. of gangue; m/S_m = volume of "mineral" per unit weight of ore; $(1 - m)/S_g$ = volume of gangue per unit weight of ore; $1/S_o$ = volume of unit weight of ore.

Then $m/S_m + (1 - m)/S_g - 1/S_o = 0$, and

$$m = 100\,\frac{S_m(S_o - S_g)}{S_o(S_m - S_g)} \tag{204}$$

Voids

Let w = weight of solid per unit volume. If material is moist, let w include also the weight of moisture. Let S = sp. gr. of dry solid, p = % solids, V = % of VOIDS = % of unit volume unoccupied when that volume contains the weight w of solid or solid + water; B = % of unit volume occupied by air, H = % occupied by water and T = % occupied by air + water. Quantities p, V, B, H, and T are expressed as decimal parts of the unit, and gram-centimeter units are most readily used.

For dry material,

$$V = 1 - w/S \tag{205}$$

For wet material pw = weight of dry solid in unit volume; pw/S = volume of solid; and

$$T = 1 - wp/S \tag{206}$$

The weight of water in a weight w of wet material $= w - pw$. Since the numbers representing weight and volumes of water are interchangeable in gram-centimeter measure

$$H = w(1 - p) \tag{207}$$

$$B = T - H = \frac{wp(S - 1) - S(w - 1)}{S} \tag{208}$$

Voids in mixed sizes. Voids in broken rock smaller than 3-in. range between 40 and 45% when fines are present and 45 to 50% with fines removed. (*Bul 5 UI # 23.*) Furnas (*RI 2894*) attempted to generalize this relationship. He found (Fig. 171) that the per-

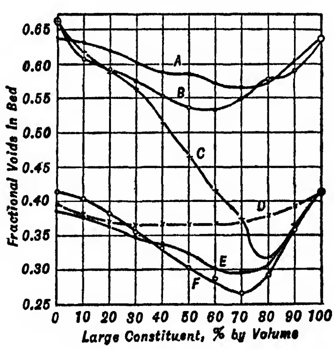

FIG. 171. Experimental determinations of voids in binary size mixtures.

centage voids differed with the size composition of the mixtures and, on the basis of these findings, presented the curves (Fig. 172) as representing the variations in voids of mixtures of two sizes of different size ratios in different proportions. Actual mixtures of broken materials of size compositions approximating these will fall consistently above the curves by amounts dependent upon the irregularity in particle shape, and the widths of the size bands of the components (see Fig. 171). The indications of the curves as to the trends of void space with size composition are, however, useful. The minima are, of course, of great economic importance in designing aggregates for concrete, in control of leaching beds, etc.

Porous materials have an intraparticle void space in addition to the interstitial void space between the particles. To determine (*RI 3047*), weigh sample in air = w_1; evacuate at 2 to 3 mm. Hg, saturate with water, and weigh in water = w_2; coat particles with paraffin at its melting point, cool, and

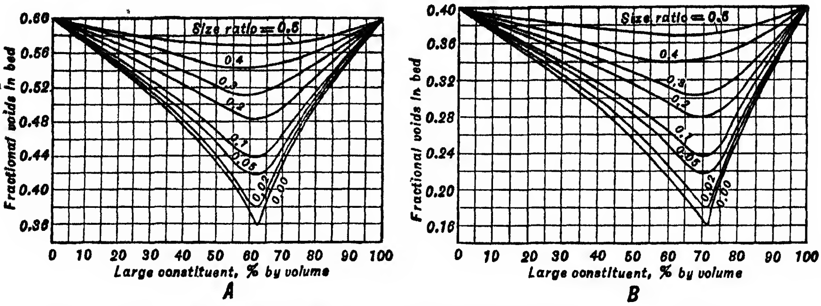

FIG. 172. Curves for design of size mixtures for predetermined void space (*after Furnas*).

weigh in air = w_3; weigh paraffin-coated particles in water = w_4. Let V denote total volume of intraparticle voids. Then

$$V = \frac{1}{G_l}\left\{w_2 - w_4 + (w_3 - w_1)\frac{(G_p - G_l)}{G_l}\right\} \tag{209}$$

where G_p = density of paraffin and G_l = density of water.

Specific volume is defined as the weight of dry solid per unit volume of broken solid and is commonly stated in lb. per cu. ft. If Q = specific volume in gram-centimeter units, m = percentage of moisture in the mass of broken solid by weight, and v = percentage moisture by volume, then the volume of actual solid + water per unit volume of broken material = $1 - V$ and the actual solid in this weight is $Q = S(1 - V)(1 - v)$. But $v = mS/(mS + 1 - m)$ (from Eq. 221), hence

$$Q = S(1 - V)\left[\frac{1 - m}{m(s - 1) + 1}\right] \tag{210}$$

In common units this becomes

$$Q = 62.5S(1 - V)\left[\frac{1 - m}{m(S - 1) + 1}\right] \text{ lb. per cu. ft.} \tag{211}$$

Pulp Consistency

Let p = decimal fraction of solids in pulp, by weight; S_s = specific gravity of solid; S_p = specific gravity of pulp; D = DILUTION = water to solid ratio by weight, usually written, *e.g.*, 6 : 1, 3.2 : 1, etc.

Then pS_p = weight of dry solids in 1 cc. of pulp, pS_p/S_s = volume of dry solids in 1 cc. of pulp; and $1 - (pS_p/S_s)$ = volume of water in 1 cc. of pulp (or weight of water if water density is unity), from which

$$S_p = pS_p + 1 - \frac{pS_p}{S_s} = \frac{S_s}{p + S_s(1 - p)} = \frac{D + 1}{D + \frac{1}{S_s}} \tag{212}$$

$$p = \frac{S_s(S_p - 1)}{S_p(S_s - 1)} = \frac{1}{D + 1} \tag{213}$$

$$S_s = \frac{pS_p}{1 - S_p(1 - p)} = \frac{S_p}{1 - D(S_p - 1)} \tag{214}$$

$$D = \frac{1 - p}{p} = \frac{S_s - S_p}{S_s(S_p - 1)} = \frac{1}{p} - 1 \tag{215}$$

The relation between p, S_p, and S_s are shown graphically in Fig. 173.

If Z = SOLID FACTOR = tons solid per FLUID TON (= 32 cu. ft.) of pulp; J = fluid tons of pulp per ton of dry solids; and q = % solids by volume, then, since the weight of 1 cu. ft. of pulp = $62.5S_p$ lb., the weight of one fluid ton = $32 \times 62.5S_p$ and

$$Z = \frac{32 \times 62.5S_p \times p}{2{,}000} = pS_p \tag{216}$$

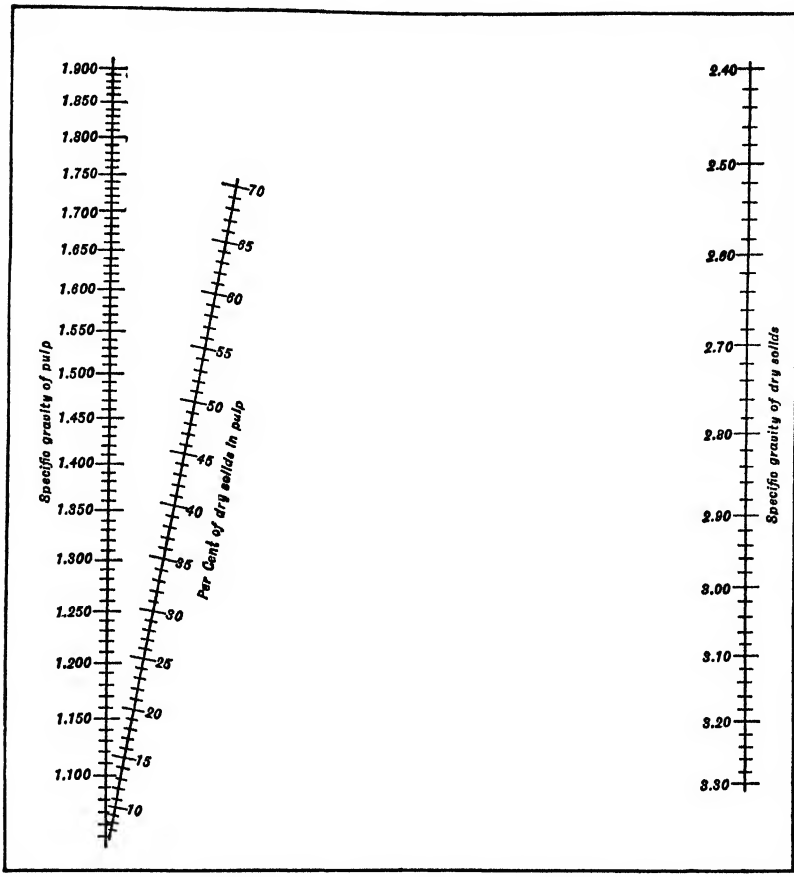

FIG. 173. Pulp density chart (*after Heinz J 457*).

By substitution in Eq. 216 of values of p and D from Eqs. 212 to 215

$$Z = \frac{S_p}{D+1} = \frac{pS_s}{S_s - p(S_s - 1)} = \frac{S_s}{DS_s + 1} = \frac{S_s(S_p - 1)}{S_s - 1} \tag{217}$$

By definition $J = 1/Z$. Hence, by Eqs. 216 and 217

$$J = 1/pS_p = (D + 1)/d \tag{218}$$

By definition $q = \dfrac{Z(2{,}000)}{S_s(62.5 \times 32)} = \dfrac{Z}{S_s}$, hence, by Eqs. 212 and 217

$$q = \frac{S_p - 1}{S_s - 1} = \frac{p}{S_s - p(S_s - 1)} \tag{219}$$

Counting Assay

If all particles are of substantially the same shape (that they are of substantially the same intermediate dimension may be assured by sizing), the volume percentages are equal to the number percentages. If there is a distinct difference in average shape of particles, the number percentages must be adjusted by factors expressing relative volumes of the mean shapes, in order to get volume percentages. If v = per cent. by volume of

"mineral" in sample = volume per unit volume, and S_m and S_g = specific gravities of "mineral" and gangue respectively, then weight of "mineral" in a unit volume of sample = vS_m and weight of gangue = $(1 - v)S_g$. The percentage of mineral by weight is

$$m = \frac{vS_m}{vS_m + (1 - v)S_g} = \frac{vS_m}{v(S_m - S_g) + S_g} \tag{220}$$

$$v = \frac{mS_g}{mS_g + S_m(1 - m)} \tag{221}$$

These formulas are applicable to mixtures of solid and water, in which case, if m and v are taken as percentages of solid, S_m is specific gravity of solid and S_g = 1.

SECTION 20

DESIGN AND CONSTRUCTION OF ORE-TREATMENT PLANTS

BY THE LATE

JOHN M. CALLOW

AND

THE STAFF OF GENERAL ENGINEERING CO.

1. SITUATION OF MILL WITH RESPECT TO MINE

General principles. Since one of the principal purposes of concentration is to reduce the expense of delivering mine product to the smelter, a concentrating mill should ordinarily be situated as close as is practicable to the source of its ore supply. In general those mines at which the ratio of concentration is high are most benefited by placing the mill near the mine, but this conclusion may be modified by one or more of the following facts: (*a*) freight rates of public carriers usually advance in direct relation to the unit value of the material carried (see Tables 8 and 9); (*b*) mill concentrate produced by wet methods may contain from 4 to 15% water, even after draining or filtering; (*c*) the site near the mine may lack adequate supply of mill water with low expense for elevation, or (*d*) suitable space for tailing disposal, or (*e*) advantageous topography for a mill site. Examples of a variety of practices are given in Tables 1 and 2.

In a large-scale operation, the ability to move great tonnages by the most efficient available motive power over privately owned track to a mill adjacent to or in the direction of the smelter may offset some of the advantages of proximity of mill to mine. Some notable examples of long hauls are given in Table 3.

Of the mills cited in Table 3, those of ANACONDA, NEVADA CONSOLIDATED, and RAY CONSOLIDATED are closely adjacent to smelters; water supply was an important consideration in selecting sites for the CHINO, COPPER RANGE, and NEVADA CONSOLIDATED mills; while the disposal of tailing contributed largely to the selection of sites for NEVADA CONSOLIDATED and the UTAH COPPER Co.'s mills. In no case, however, was the decision based upon one favorable condition alone.

Placing a mill near the mine it serves tends to minimize irregularities in receipt of ore. Mill stoppage for lack of ore can be guarded against to a limited extent by providing storage bins, but it is seldom practicable to store more than two or three days' supply, and some large mills would have to cease operations if the ore supply were interrupted for a single day (see Table 13).

Methods of Transporting Ore to Mill

The following means are available: (1) Mine-car or other small-car tramming: (*a*) hand; (*b*) animal; (*c*) cable; (*d*) storage-battery locomotive; (*e*) trolley locomotive; (*f*) gasoline and/or Diesel locomotive; (*g*) narrow-gage steam locomotive; (*h*) mono-rail system. (2) Wagon or truck haulage: (*a*) animal; (*b*) motor trucks; (*c*) tractors and trailers. (3) Belt conveyors. (4) Aerial tramway: (*a*) reversible; (*b*) continuous. (5) Standard-gage railroad.

Hand tramming is frequently adopted at small mines for distances up to 300 ft., especially when the mine cars themselves can be conveniently trammed to the mill. The track can usually be maintained in better condition than underground, and can be laid to the most advantageous grade, say 0.6% in favor of the loaded run. On well-graded track, with the usual metal-mine car in good condition, one man can push a net load of 2,000 lb.

a By steamer.

at a speed of 1 1/2 mi. per hr. (130 ft. per min.); maintaining the same speed on the return trip would give an ore-carrying capacity of 0.75 ton-mi. per hr. *in motion.* Dumping time, which is approximately 1/2 min., will range from 40% of the total working time (excluding loading) on a 50-ft. tramming distance to 10% on a 300-ft. tram. Loading time will vary between the extremes of 2 min. (from chutes) to 30 min. per ton (shoveling from rough bottom). (For further data on loading and tramming by hand, see *Peele.*)

Animal tramming is applied to trains of mine cars, and also to one or several cars of large size receiving ore from a dumping or storage pocket. The method is not more efficient than hand tramming over short distances and for traffic of less than 2 ore-ton-mi. per hr., but competes favorably with mechanical systems up to 25 ore-ton-mi. per hr. at distances up to 1/2 mi. and with grades below 1.25%. On good track, with moderate grades in favor of the load, one mule can pull a gross load of 7 to 12 tons, and haul from 2 to 4 ore-ton-mi. per hr. of total working time at distances of 700 to 3,000 ft. The tractive force of an average horse, at 2.5 mi. per hr. for 8 hr. is 125 lb.

Cable haulage may be applied to gravity-plane, engine-plane, or tail-rope system.

Gravity plane. Loaded cars, of modern design and well lubricated, will run freely down a grade of 2%, but if empty cars are to be hauled up by the action of the descending loads,

f While costs of fuel and labor have increased in the interim, improvements in plant and economies in operation substantially offset the increase.

transmitted through a cable, 5 to 5 1/2% is about the minimum grade that will operate with a plane 500 ft. long; longer planes require steeper grades, up to 10 or 15%. Cars or skips discharging automatically into a receiving bin at the bottom of the incline are frequently used.

Engine plane may be operated on any grade steep enough to allow the empty trip to descend by gravity, while overcoming the added friction of cable and engine drum. In practice, 3 1/2% has been found to be the minimum satisfactory grade.

The Nipissing low-grade mill, at Cobalt, received part of its ore by an engine plane 2,200 ft. long, hauling a trip of 4 cars, or 3.85 tons of ore, up a steady grade of 10%, with a 30-hp. electric hoist and a 1/2-in. cable. Operating at 90% capacity, the plane made one trip in 25 min. The total cost of operation (1922) was 34.2¢ per ton hauled, or 82¢ per ton-mi. The cost of installation, in 1913, was $6,500. At the Trojan mine, S. D., one electric hoist was used both to haul trips of eight 1.5-ton cars up a 1,500-ft., 6% slope out of the mine, and to lower them 2,000 ft. down a 15% incline to a gathering station from which they were hauled to the mill by gasoline locomotive.

Tail-rope system is best adapted to nearly level or irregular grades, and can be applied to curved track; it is commonly used at coal mines.

A well-known application to surface tramming in the United States is in the Tri-State district, hauling ore from one or more outlying shafts to a central mill, an average distance of 800 ft., with 1/2 mi. as a maximum (10-ton steam and 5-ton gasoline locomotives are used for the same service). Track is 36-in. gage with 40-lb. rail, and cost (1923) an average of $1.56 per ft., including grading, laying, and all track materials. Cars are of steel, with roller bearings, and of 2.5- and 3.5-ton capacity (44 and 62 cu. ft.). At Golden Rod mill (H. H. Wallower, *PC*) a 14-car train with gross weight of 60 tons was hauled by a tail-rope system a distance of 1,800 ft. over level track containing frequent curves. The driver was a band-friction, tandem, double-drum hoist, belt-driven by 75-hp. motor; after starting, little power was needed. A total of 144,000 tons was trammed in 1923 at the following costs per ton: Labor, 4.09¢; power, 0.27¢; supplies, 1.824¢; total, 6.18¢; total cost per ton-mi., 18.13¢.
Limitations of the tail-rope system as to grades and distances have not been reached in the Tri-State district; curves present slight difficulty.

Belt conveyors are frequently used for bringing ore into a mill from a hoist pocket, train-dump pocket, or coarse-crushing plant. They may also serve for hand-picking of the ore in transit, and to elevate to the top of the mill. For details of construction, see Sec. 18, Art. 6. With a 36-in. belt, and material of 100 lb. per cu. ft., 1 ton-mi. of transport on level ground requires 1.25 hp.-hr. of work; in general, for lighter materials and narrower belts, 1 hp.-hr. moves 1 ton 1 mi. on a level haul.

A downhill belt conveyor was installed by the Mountain Copper Co. to convey the pyrite output of its Hornet mine, crushed to 4-in. maximum size, a vertical distance of 189 ft. from mine level to railroad track in a horizontal distance of 300 ft. The two terminal bins and an intermediate tower bin supplied all but 60 ft. of the vertical drop, which was divided between two conveyors. The upper, 24 in. wide, sloped 9° 40′ and traveled 125 ft. per min., governed by a small motor and two sets of spur gears; the lower, 20 in. wide, sloped 14° 40′, traveled 150 ft. per min., and was connected to the same shaft

that drove a trommel (*119 P 638*). In a similar manner, at the ENGELS mill (*123 P 183*) flotation concentrate (70 tons, dry, per day) carrying 10 to 15% water was lowered a vertical distance of 100 ft. on a 12-in. belt sloping 34°.

For further data on practice, see Sec. 2, various mills; and Sec. 18, Art. 6.

Mono-rail system, well developed in Europe, has only one noteworthy installation in the United States, *viz.:* near Searles Lake, Calif. (*116 J 100*).

The total length is 28 mi. of which 8 mi. is level but the remainder traverses extremely rugged country, requiring sharp curves and grades of 8 to 10%. The wooden framework supporting the rail is seldom more than 3 ft. high. Estimated cost was $8,000 per mi. A specially fitted Fordson tractor makes 10–15 mi. per hr. on the level, and 8 mi. per hr. upgrade. Cost of transportation was estimated at less than $1 per ton.

Horse-drawn wagon haulage. For general data on loads, speeds, grades, tractive resistance, road surfaces, etc., see *Peele*.

At Philipsburg, Mont., the ALGONQUIN mine formerly shipped manganese ore 2.7 mi. to the mill by 6- or 8-horse wagon and trailer carrying together 5 to 6 tons. The team made two round trips per day. In the DOLORES district, Colo., picked vanadium ore was hauled on contract by 4- or 6-horse wagon and trailer 50 to 90 mi. to Placerville. The average load was 1,000 to 4,000 lb. per horse, depending on grades and road condition. Speed on rough roads, 16 mi. per day; on good roads, 22 to 25 mi. per day. During the early development of the MAGMA mine (1914) the rate for wagon haulage of supplies, 32 mi. upgrade from Webster, was $10 per ton; when the wagons hauled both ways the rate was $8 up, $5 down.

Motor trucks have largely supplanted horse-drawn wagons where the roads are suitable; tractors and trailers can be used where horse-drawn loads cannot get through.

Table 4 (*IC 6898*) gives low and high average costs of trucking. Differences are due to amount of material handled, condition of roads, grades, method of loading and unloading, cost of supplies, and condition of equipment.

Table 4. Average costs of trucking, cents per ton-mile

Distance hauled, miles	2	5	10	20	50	100
Low average	18	11	8	6	5	4 1/2
High average	....	32	23	16	10	7 1/2

With the rapid improvement in roads, the use of gasoline and Diesel trucks is increasing. Trucks of 30-ton load capacity and larger are coming into use.

The COLUMBIA STEEL Co. in Utah, using 30-ton trucks, loaded by steam shovel, is hauling iron ore one mile to the crushing plant. At Tooele, Utah, 20-ton trucks haul lime sand for smelter flux a distance of about 15 mi. At MORENCI (*23 M Mt 251*) 22 1/2-cyd. trucks were used for the preliminary work in the open pit. They were originally equipped with gasoline engines, but these were replaced by Diesels, which cost less for maintenance and operation. Average operating cost per truck per 8-hr. shift was $35, including labor (one driver), lubricant, fuel, and all maintenance. Tire mileage was 12,000.

Tractors and trailers move at relatively slow speed, but can haul heavy loads over roads rough enough to be damaging to motor trucks.

At Philipsburg, Mont., the ALGONQUIN mine shipped manganese ore 2.7 mi. to the mill in trains of five 6-ton trailers drawn by a 75-hp. Holt caterpillar tractor, making three trips a day, at a cost of 72¢ per ton, or 27¢ per ton-mi. TREADWELL-YUKON Co., Mayo district, Yukon Terr., employed a 10-ton Holt caterpillar tractor to haul 4 sleds loaded with 33 to 54 tons of sacked ore a distance of 42 mi. down very rough mountain road, with frequent grades that required splitting the load. During 5 months (Nov. 1922 to Mar. 1923) the train made 54 round trips (4,636 mi.) delivering 2,501 tons of ore (46 tons per trip). The temperature ranged from +10° to −50° F. and snow was 4 ft. deep on the level but there was no interruption to tractor service. The loaded trip required 20 to 24 hr., the return trip with a light load of supplies, 16 to 20 hr. Gasoline consumption was 2 gal. per mi. loaded; 1 gal. per mi. returning. Total cost (fuel, oil, and wages, including return trips) was $2.60 per ton, or 6.2¢ per ore-ton-mi.

Gasoline locomotives are built up to 15 tons in weight, with drawbar pulls of 20% of their weight and geared to speeds of 6 to 12 mi. per hr. The makers estimate gasoline consumption at 0.1 gal. (0.6 lb.) per hp.-hr.; tests have indicated 0.73 to 1.2 lb. of gasoline per brake hp.-hr. at full load and full speed, 1.2 to 2.2 lb. at half load and half speed, and higher consumptions for reduced loads.

At numerous bituminous-coal mines and a few metal mines of the United States (*Peele*) with hauls of 1,800 to 8,400 ft., the operating cost ranges from 2.5 to 5¢ per mineral-ton-mi.

At the NEW YORK ZINC Co., Edwards, N. Y. (*W. R. Wade, PC*), a Fate-Root-Heath 25-hp. gasoline locomotive hauled a train of two or three cars, each weighing 3,000 lb. empty and carrying 3 tons of ore, an average distance of 800 ft. down a 0.5% grade at a speed of 15 mi. per hr. Track, 2-ft. gage with 25-lb. rails. The locomotive also hauled waste (about one-fourth of the ore tonnage) an average

distance of 400 ft. In a 9-hr. shift, it averaged 250 tons of ore and waste. Gasoline consumed, 1 gal. per hr.; estimated operating expense (excluding wages), $2 per shift; repairs, not over 0.1¢ per ton. Allowing wages of $4 a day for one engineer, the estimated total direct cost for haulage only was 17.7¢ per ton-mi. The first cost of the locomotive was $1,815. At the TROJAN mine, S. D., a Milwaukee gasoline locomotive hauled trains of eight 1.5-ton cars a distance of 2,000 ft. to the mill at cost of 6¢ per ton (1922) or 15.8¢ per ton-mi.

Diesel locomotives, owing to their higher thermal efficiency and cheap fuel, have almost entirely replaced gasoline-driven locomotives. They are built in all sizes from 3′ to 30-ton upward, and are motored from 6–7 hp. per ton on the smaller to 7–8 on the larger sizes. Fuel consumption ranges from 0.4 to 0.6 lb. per b.hp.-hr., as against gasoline consumption of 0.8 to 0.9 lb. per b.hp.-hr.

Diesel locomotives have been used in coal mines and other confined and badly ventilated places in Europe since about 1933, by equipping them with exhaust-washing or conditioning apparatus. About 1,000 such machines are in use in France and Germany alone at this time (1938). A concentration not exceeding 0.1% CO is guaranteed continuously, and where firedamp (methane) is encountered, stainless-steel flashproof grills (Davy-lamp principle) are fitted on the exhaust to guard against explosion. Exhaust gases, either before or after passing the grills, are passed through a cooling tank containing water. Some makers recommend adding an oil solvent to purify the exhaust by retaining the carbon particles. Spent cooling solution is changed at intervals of 8 to 12 hr.

Table 5. Comparison of Diesel and other rail-haulage costs in France

[After Rice and Harris, *RI 3320*, quoting *Georges Scherrer*]

	Electric trolley	Storage battery	Diesel	Rope haulage
	¢	¢	¢	¢
Wages and fixed charges	1.056	2.046	1.056	2.178
Electric energy, fuel, etc	0.924	1.122	0.792	0.858
Total costs	1.980	3.168	1.848	3.036
Total costs per ton-mile	2.88	4.61	2.70	4.45
Cost for an installation capable of hauling 1,500 ton-km. per shift	$19,800	$49,500	$16,500	$19,800

Narrow-gage steam locomotives are found in many districts, hauling for long distances, where rough topography makes construction of standard-gage roadbed unjustifiably expensive. A simple steam locomotive consumes 4.5 to 8 lb. of coal or 2 to 5 lb. of fuel oil, and 27 to 32 lb. of water per hp.-hr. while in motion; the total fuel consumption, covering delays, may be 50 to 100% greater.

At BAWDWIN MINES, Burma, the total length of narrow-gage line is 46 mi. with grades of 4 to 5.5% in places and numerous sharp curves. Gage is 2 ft. The principal traffic is downgrade, 33 mi. at a cost of 7¢ per ton-mi.

Storage-battery locomotives might be advantageous to haul trains of ore cars directly to the mill from a mine in which battery locomotives for any reason are preferred underground. Gages range from 18 to 44 in. In general, battery locomotives are equipped with motors aggregating 4 hp. per ton of total weight; the range is from 2.5 to 8 tons. On clean rails they exert a drawbar pull of one-fourth their weight when moving at 3 1/2 mi. per hr.; they have been operated effectively on grades up to 10%, but in general they give best results on moderate grades.

In the BUTTE & SUPERIOR mine, in narrow, tortuous drifts with irregular grades (*123 P 751*), a 3 1/2-ton locomotive, exerting a drawbar pull of 1,500 lb., at 4 mi. per hr., hauled a train of 10 roller-bearing cars, each of 2,250 lb. gross weight. During 1919, nine locomotives hauled 737,787 cars of ore and waste an average distance of 790 ft., at cost per car-trip of: power, 0.41¢; locomotive repairs, 3.21¢; motorman and helper, 6.90¢; total, 10.52¢.

Exhaustive tests at COPPER QUEEN showed that battery locomotives required 1.6 kw.-hr. at the powerhouse per ore-ton-mi. In the UNITED VERDE mine (*66 A 177*) Baldwin-Westinghouse 3-ton locomotives gave a drawbar pull of 800 lb. at 3 1/2 mi. per hr. Batteries (80 Edison A-4 cells) were recharged after each shift, with 250-volt current. Hauling 215 tons ore per shift, a distance of 200 ft. up 0.4% grade, the cost in cents per ton was (1918): Labor (1 motorman and 2 loaders), 8.4; power (25 kw.-hr. per shift), 0.4; depreciation of motor, 0.6; repairs and inspection, 0.2; total, 9.6¢.

Trolley locomotives, in addition to hauling trains of ore cars direct from mine workings to the mill, where this is possible, are often installed independently for surface haulage from

a loading pocket at the mine, as at ALASKA-GASTINEAU, BRITANNIA, HEDLEY, MELONES, TONOPAH EXTENSION, BUNKER HILL & SULLIVAN, and many other mines. For this purpose, more powerful and wider-gage locomotives are applicable than for mine haulage, and higher voltages are permissible. Trolley locomotives are usually equipped with motors aggregating 10 hp. per ton of total weight (which ranges from 3 to 30 tons), and give a drawbar pull, with steel-tired wheels, estimated at 25% of the total weight of the locomotive.

At UNITED VERDE mine, Jerome, Ariz. (*66 A 177*), in the Hopewell main-haulage tunnel, 25-ton Baldwin-Westinghouse locomotives were used, equipped with two 75-hp. 250-volt, direct-current motors and exerting a drawbar pull of 12,500 lb. at 7.1 mi. per hr.; total haul, 8,900 ft. Bottom-dump, standard-gage cars of 220-cu. ft. nominal capacity were loaded from chutes with 280 cu. ft. or 20 tons of heavy sulphide ore. The trains were 14 cars, making 425 tons gross per locomotive. The cost in cents per ton for 1918, on 861,250 dry tons, was: Labor, including loading and dumping, 5.4; supplies, 0.1; power, 0.5; repairs, 3.5; total, 9.5, or 5.6¢ per ore-ton-mi. At ALASKA-JUNEAU (*120 P 251*) the mine output was hauled 2 mi. down a 0.5% grade, 30-in. gage, double-track, 32-car trains; each car weighed 3 tons empty and carried 10 tons of ore; total weight of train, 96 tons empty, 416 tons loaded. The locomotive was in two sections, of 9 tons each, having two direct-current Westinghouse No. 905 motors in each unit and was small enough to pass through a rotary car dump discharging four cars at a time. The front section of the locomotive could be quickly detached and used for switching. Power for operation was obtained from two 300-kw. rotary converters, each with an individual 6-phase transformer.

The BUTTE, ANACONDA & PACIFIC RY. transports ANACONDA ore (over 5,000,000 tons per year) from mines on Butte Hill to the Washoe concentrator at Anaconda; total haul, 32 mi. (*Elec. Ry. Jour.*, Mar. 14, 1914). The General Electric locomotives used weigh 80 tons, have 1,050-hp. continuous rating, and exert a tractive force of 25,000 lb. at 15 mi. per hr. Trolley wire is No. 0000 and carries 2,400 volts direct-current. The cars weigh 18 tons and carry 50–53 tons of ore; two locomotives per train. Operating data are given in Table 6.

Table 6. Haulage of Anaconda ore by Butte, Anaconda & Pacific Ry.

	On Butte Hill, mines to Rocker	Main line, Rocker to E. Anaconda	On Smelter Hill, E. Anaconda to concentrator
Distance, miles	4.6	20.1	7.2
Average grade, loaded	−2.5%	−0.3%	+1.1%
Cars in train	30	65	20
Gross train load, tons	2,000	4,620	1,400
Speed, miles per hour	12	16–21	16

This road, formerly steam-operated, was electrified during 1912–13, at a cost of $1,201,000; the first year's electric operation indicated a saving of 36% in direct costs, as shown in Table 7. In the item of power alone, the saving was 48% compared with steam operation. The saving in trainmen's wages was due principally to the higher speed and greater regularity in train movement.

For other data on performance and operating costs of trolley locomotives, see *Peele*.

Table 7. Comparative costs of steam and electric haulage at Anaconda

	1913, steam	1914, electric
Locomotive operation only (fuel or power, oil, crew, maintenance, etc.)	$594,921	$357,339
Trainmen's wages	147,632	116,486
Total direct operation	$742,553	$473,825
Ton-miles hauled, net	158,917,720	172,855,856
Cents per ore-ton-mile	0.467	0.274

Standard-gage steamlocomotives are employed by the largest mines, not only for long hauls of ore but also for disposal of waste. In many cases, the tracks form part of the mine equipment; in others, the roads serve as public carriers operated by organizations subsidiary to the mining companies; while in others, the ore traffic runs partly or entirely over independent roads, sometimes under a trackage license. A few notable examples of relatively long hauls over standard-gage railroads were given in Table 3. Tables 8 and 9 give rate data useful for preliminary estimates; published tariffs should be consulted for final estimates.

Moisture in the ore or concentrate must be included in figuring freight. For freight purposes, the value of ore is the net amount per ton paid by the smelter to the shipper less the freight per ton, not deducting the smelter treatment charge.

Freight rates for metallic products such as slab zinc, lead bullion and pig lead, copper bullion and refined copper, Inter-Mountain States to Atlantic seaboard, may be estimated at 0.5¢ per ton-mi.; to Pacific seaboard, 0.8¢ per ton-mi.

Table 8. Freight rates on ores and concentrates charged by certain common-carrier railways, September 1923 (116 *J* 480)

a Narrow gage.

Ocean rates, New York to Atlantic European ports, $6.00 to $7.00 per gross ton; Gulf ports to Atlantic European ports, $4.50 to $5.00 per gross ton; Pacific ports to China (Hong-Kong), $5.00 per short ton; Pacific ports to Japan (Kobe), $4.00 per short ton.

Copper Queen hauled waste rock from Sacramento Hill downgrade to a dump 2 mi. away (*68 A 251*). Of 15 standard-gage Porter locomotives used (4 driving wheels and saddle tanks), three weighed 53 tons each and exerted a tractive force of 20,436 lb.; the other 12, with superheaters, weighed 54.5 tons each and exerted 23,063 lb. pull; gage pressure, 175 lb. in both cases. Cars were all-steel with compressed-air dump, had capacities of 20 and 25 cu. yd., and weighed, respectively, 55,400 and 60,700 lb. The average performance per locomotive-shift was 450 cu. yd. (solid; estimated at 1,035 tons) at a cost of 17.7¢ per cu. yd., or 3.8¢ per ton-mi.

Estimation of size of simple locomotives for a given service depends on providing an excess of tractive effort over the frictional resistance of train and locomotive. Maximum locomotive drawbar pull with steel-tired locomotive wheels ranges from 25% of locomotive weight on dry track to half that figure on wet track. Frictional resistance of train and locomotive in motion ranges from 10% of their combined gross weight with roller- or ball-bearing axles to 20% with plain axles. Starting resistance on level track, particularly after standing some time in cold weather, may be double these figures, but under favorable conditions after a momentary stop may fall to 3% above rolling resistance. Starting resistance is less with spring drawbars, which permit the load to be picked up gradually. Cars weigh from 40 to 50 lb. per cu. ft. of loadable ore capacity; a rough figure for estimate is one-third of gross train load.

Table 9. Average freight rates on ores, Inter-Mountain States, 1938

Miles	Smelter value of ore in dollars per ton

Reversible aerial tramways are designed for distances up to 2,000 ft., and bucket loads of 400 to 2,500 lb. Intermediate supports may be used, but the speed is then limited to 1,000 ft. per min.; on an unsupported span, 1,500 ft. per min. is safe. There may be one or two carrier cables; in the latter case the economical limit is approximately 20,000 ft.-tons per hr.; for a single cable the capacity is less than 10,000 ft.-tons per hr. (*Peele*).

At Siscoe Gold Mines (*57 CMJ 498*), a shuttle tramway transports 400 tons of ore per day from crushing plant to mill (800 ft.). The equipment consists of a bucket of 2.05-ton capacity fully loaded, two 1 3/8-in. track cables, one 1/2-in. endless haulage cable, central supporting tower, and an anchor tower. The system is operated by a 15-hp. motor through a herringbone-gear speed reducer. Average speed of bucket is 715 ft. per min. Average total time of trip, including loading, tramming to mill bins, unloading, and return, is 3 min. The full efficient capacity is 41 tons per hr. Average life of track cables is 3 1/2 yr., haulage cable lasts 1 yr., average tramming time is 315 hr. per mo. Cables are greased monthly. The cost of crushing, screening, conveying, and aerial tramming was 12.7¢ per ton (January to March 1936).

At the Ottawa mill, near Slocan, B. C., a two-bucket reversible gravity tram 200 ft. long, with rated capacity of 10 tons per hr., cost $8,000 in 1921, including the erection of terminals and clearing of way. Rugged country and local scarcity of timber added to the expense. Cost of tramming was 10¢ per ton.

Continuous aerial tramways often afford the only practicable means of conveying ore from the mine or concentrates from the mill in steep or rough districts. The economical minimum limit of capacify is 10 tons per hr.; the maximum limit ranges from 100 tons per hr. in general to 200 tons under exceptionally favorable conditions. They are not usually warranted for distances of less than 1,000 ft. and the maximum length of a unit is about 4 mi.; two or more units can be erected in tandem, with transfer of buckets for greater

distances. Anchor and tension stations must be situated at intervals of 3,000 to 5,000 ft. Loads per bucket range between 500 and 2,000 lb., and three buckets per min. is about as rapidly as they can be handled at terminals; two buckets per min. is nearer the average. (For additional data see *Peele.*) Data on specific operations are given in Table 10.

Cost of aerial tramways varies greatly in different sections of the United States. Tramways having capacities of 35 to 50 tons per hr. have been built for as little as $4.25 per ft. This cost can be approached only where it is possible to get an abundance of skilled labor at a reasonable rate, and where it is possible to deliver all construction material by truck or some other low-cost method. The other extreme is probably represented in southwestern Colorado, where there is a scarcity of almost

everything required and where much of the material for construction purposes (even water for concrete) must be delivered by pack animals. Here a dependable tram will cost $10 per ft. or more. A lighter and less substantial tram might be built for $8 per ft., but such a tram could not be depended on to operate successfully during the severe storms that prevail in winter. Other things being equal, a short tram costs more per foot than a long one, since terminals represent a large percentage of total cost (*IC 6948*).

Table 11 gives costs of equipment for tramways of standard American make for capacities of 25 to 100 tons per hr. The data do not include the cost of supporting structures or installation costs. For lines requiring braking and control equipment, $175 to $850 must be added.

Construction and installation costs will range from equality with the equipment cost where topography is favorable and labor supply and material plentiful to two or three times the equipment costs under unfavorable conditions.

At Hollinger, 2,500 tons of sand and gravel for mine backfill is handled per day over a mono-cable aerial tramway 3.6 mi. long (*56 CMJ 418*). The tramway consists of a single endless rope passing around a terminal sheave at each end and kept in continuous motion by a 100-hp. motor through belt, pulley, and reduction gear. There is 100 ft. difference in elevation between loading and discharging terminals. The cable is driven at the mine end by an open-groove friction sheave equipped with a sectional lining of 1-in. cast copper blocks (which lasted 40 times as long as the original lining of leather and brake-band material). Tension is maintained at 26,000 lb. by a weight at the lower terminal. There are 69 steel towers averaging about 28 ft. in height. The rope carries 227 @ 19-cu. ft. buckets having a nominal capacity of 1,900 lb. each. At a rope speed of 527 ft. per min. a bucket makes a round trip every 70 min. Maximum capacity is 190 tons per hr. Average life of cables is about 1,200,000 tons. Cable is 1 5/16 in. diameter, Lang-lay, 6 strands of 15 wires each, and weighs 2.75 lb. per ft.; breaking strength, 58 tons; wire tensile strength, 198,000 lb. per sq. in. Idler sheaves are mounted on rocker arms on the towers. Sheaves are provided with Alemite lubrication while the cables are oiled automatically by a drip can. Cost of operation (1934) was 2.10¢ per ton of sand delivered; cable maintenance and replacement was 1.60¢ additional, loading and unloading buckets amounted to 2.79¢; total, 6.49¢ per ton.

Table 12 presents data concerning haulage performances, compiled from a variety of sources.

Table 12. Summary of haulage practices

a Large reserve storage in mine.
b "Available" storage only, including 2,500 tons in 3 ore trains; actual cubic capacity of storage bins for crushed ore is 50,000 tons.
c Utah Copper Co. has no storage bins for uncrushed ore, but loaded cars standing or in transit contain 26,000 tons.

Storage for ore must be provided to insure uniform rates of feed to crushing and grinding units. The necessary bin capacity depends upon the degree of uniformity of the stream of ore from the mine chutes, the working periods of mine and mill, climatic conditions, requirements for mixing ores, and other less important considerations (see Sec. 18, Art. 1).

Run-of-mine ore is difficult to handle in cars or skips and from bins. To lessen such handling, coarse crushers are sometimes installed underground. The cost of such crushing is slightly higher than at the surface, but it reduces labor at loading pockets and wear in chutes and skips, and it permits coarser breaking in stopes.

When crude ore is supplied at a uniform rate, as by mine skip from an underground storage pocket, a pocket to hold one or two skip loads ahead of the crusher is sufficient. Other mine conditions may require crude-ore bin capacity of 24-hr. supply or more. Usual practice is to operate the coarse-crushing plant for 8 or 16 hr. per day only, to allow at least one shift per day for uninterrupted entry of supplies to the mine, and to permit normal crushing-plant repair without interference with movement of ore by the mine. This practice necessitates storage between the crushers and the 24-hr. operations.

Where ore comes to the coarse-crushing plant by train, as at UTAH COPPER and other mines, the cars provide coarse-ore storage.

The secondary, or crushed-ore, storage must be sufficient for continuous 24-hr. operation of grinding and concentration units. The capacity of crushed-ore bins will depend upon the operation of the coarse-crushing plant, the method of distribution of the crushed ore in these bins, and any mixing requirements. Average crushed-ore bin capacity is about 24-hr. supply; it runs as high as 72 hr. in some cases.

Table 13 gives data on some well-known mills.

2. WATER SUPPLY

Usual sources of plant supply are: nearby streams, lakes, or irrigating ditches, wells or tunnels tapping water-bearing strata, seepage from tailing piles, or the mine itself.

Water requirements depend, of course, on the kind and variety of demand. In isolated camps provision must be made not only for the mill supply but also for the domestic supply, fire protection, the mine, and possibly a smelter and power plant. Of these demands, that by the mill itself predominates as to quantity, while the power plant, and, even more, the domestic demand set relatively high standards as to quality.

Mill requirements are so large that adequate supply often becomes an important engineering problem; in many cases it has been the deciding factor in the selection of a millsite. Where railroad connections permit cheap haulage, it has frequently proved economical to bring crude ore many miles to a convenient source of water instead of pumping the required amount of water to a mill in the neighborhood of the mine. Even with an abundant supply of water in proximity to the mill, if the water must be lifted a considerable height to mill storage, it becomes an important factor in mill design and location because of the large ratio of water to ore (2 to 20 : 1) in mill pulps. In flotation mills the chemical composition and uniform character of the water supply are of prime importance.

The nature of the process and of the equipment are the primary determinants of the quantity of mill water required. Washers require the most; then, in decreasing order, jigs and tables, flotation, and hydrometallurgical processes. The amount of new water required depends upon the method employed, if any, for recovering clarified water from mill products. Water recovery is, naturally, most common in districts where water is scarce; also at mills where soluble reagents have value; but the desirability of clarifying and recovering water at any convenient stage in the milling system, at an elevation above that of final discharge, always deserves investigation. Data on water requirements of representative mills are given in Table 14.

Domestic consumption in American cities averages about 100 gal. per day per capita; the range is from 30 to 200 gal., depending on supply, percentage metered, and nature of industries. Maximum daily consumption may exceed the mean 40 to 50%; maximum hourly consumption is determined largely by fire service and may be three times the mean daily average. In dry or arid regions consumption is, of course, fixed by the amount of water available, and may be held well below the above 30-gal. minimum. Mine requirements are comparatively negligible in quantity. Smelter and power-plant requirements are highly specific.

Supply. Rainfall and evaporation vary with the locality and differ greatly for the same locality from year to year. U. S. Weather Bureau records give the following values of mean annual rainfall over a period of nearly 30 yr.: Vicksburg, 53.8; New York, 43.7; Chicago, 33.4; Omaha, 30.8; Helena, 13.3; Yuma, 2.7.

Table 15 shows the necessity of having records extending over a period of years.

Evaporation depends on the quantity and distribution of rainfall, temperature, barometric pressure, and nature of vegetation. For New Jersey, Vermeule (*U. S. Geol. Surv. of N. J.*, 1894, *vol.* 3, *p.* 76) gives $E = F(15.50 + 0.16R)$ where E = yearly evaporation in in., $F = (0.05T - 1.48)$, T = mean yearly temperature, °F.; R = yearly rainfall, in. In arid regions evaporation may account for the entire rainfall.

Runoff and yield. Runoff from a watershed is the amount of water that reaches streams which drain the shed and is the difference between rainfall and evaporation. YIELD is the collectible portion of rainfall and cannot be computed accurately until the following data are known: (1) catchment area, (2) rainfall, (3) minimum year and a series of years, (4) available storage capacity on streams, losses in

evaporation and percolation, (5) measurement of actual discharge of streams. Runoff in New York and New England averages about 45% of rainfall, but the percentage may vary 100% for the same annual rainfall. Average yield is nearly 1,000,000 gal. per day per sq. mi. Small watersheds give a smaller yield per sq. mi. than large ones. For the Pacific States Gunsky determined that the runoff may be expressed in identical percentages of precipitation expressed in inches, *i.e.*, if rainfall is 25 in., runoff is 25% or 6.25 in.; if rainfall is 10 in., runoff is 10% of 10 or 1 in.

Ground water is that part of precipitation, termed RUN-IN, which soaks into the ground. Sands and gravels permit large run-in, clay is nearly impervious. In Connecticut the run-in is 50% of the rainfall, in New South Wales, 2%. Ground water is a source of supply to wells and springs, and to streams except immediately after precipitation. For the same annual rainfall, the ratio between run-in and runoff is a factor of supreme importance in water-supply problems. A high percentage of run-in makes uniform flow in streams and gives abundant supply to wells; low run-in makes arid regions because most of the rainfall finds its way immediately to the water courses and is lost, unless excessive storage capacity is provided. Desert regions are characterized by water courses that are dry except during the period immediately after rain when the water passes off in a flood.

Wells. The horizon below which soil is saturated is called the WATER TABLE. This horizon fluctuates in height with the amount of rainfall and is, in general, parallel to, and a few feet below, the ground surface. Wells sunk below the level of the water table are a source of supply, the yield depending on the ground water present and ease with which it can flow through the neighboring soil; this depends on the nature of the soil, topography of the country, and geologic features of the rocks. ARTESIAN WELLS are those sunk through the first impervious layer to lower water-bearing strata in which the water is under pressure. FLOW FROM WELLS can be determined only by tests and by records of existing wells in the vicinity. Long records are desirable since flow may decrease rapidly with time.

Pumped wells are usually drilled 8 to 24 in. in diameter and are equipped with turbine pumps; capacities up to 10 sec.-ft. are available. EFFICIENCIES range from 60% for small deep wells to 85% for large shallow wells.

Costs of drilling and casing wells vary according to location and ground. Average costs are given in Table 16.

Table 16. Average cost, drilling and casing wells

Material	Diam. of well, in.	Type of casing	Approx. cost, drilling and casing, per ft.
Gravel envelop			For bad sand conditions, cost varies so much as to make estimate impracticable.
Earth, sand, up to 200 ft	8	Screw	$2 to $3 *a*
	12	Screw or single welded	$2.50 to $3.50 *a*
	16	Single welded	$3 to $5 *b*
	20	Single welded or riveted	$6 to $8.50 *b*
Boulders, shale, up to 200 ft	8	Screw	$2 to $3 *a*
	12	Screw or single welded	$3 to $4 *a*
	16	Single welded	$5 to $8 *b*
	20	Welded or double riveted	$6 to $10 *b*
Soft rock			Add $1 per ft. to earth prices.
Hard rock			2 to 5 times soft rock, usually drilled on a per diem basis.

NOTE: Wells under 200 ft. may be classed as shallow, those over 500 ft. as deep.

a Add 50¢ per ft. for each 100 ft. below 200 ft.
b Add $1 per ft. for each 100 ft. below 200 ft.

Stream flow is the usual source of water supply. Stream-flow records covering several years are necessary for dependable estimates of possible yield of a region. When records for short period only are available, rainfall records for the same period should be compared with the runoff record and with the rainfall record for a dry season. When no stream records are available, monthly rainfall records must be used, making allowance for evaporation, deep seepage, and other possible losses. To determine probable fluctuation in flow, rate of precipitation must be considered and ratio of run-in to runoff estimated from topographic features, soil, and vegetation.

Storage is impounding of water during periods of maximum flow for use during dry periods. The usual method is to build a dam in a narrow valley, or a series of such dams on tributaries wherever natural storage sites occur. The storage necessary to assure any assumed continuous draft is determined by study of stream-flow records.

In Fig. 1 the minimum draft can be raised from line A–B to line C–D by supplying storage equal to the larger shaded area representing excess of demand over supply. The height of line C–D increases with the capacity of the reservoir until it equals the mean annual flow minus evaporation and leakage. EVAPORATION LOSSES from a reservoir are 30 to 100 in. per yr., the high figure applying to arid regions.

Example. If a hydrograph is plotted with a vertical scale of 1 in. = 1,000,000 gal. per day, and horizontal scale of 1 in. = 1 month, each square inch of area will represent 30,000,000 gal. The total storage area × 30,000,000 plus the estimated losses gives the REQUIRED STORAGE CAPACITY.

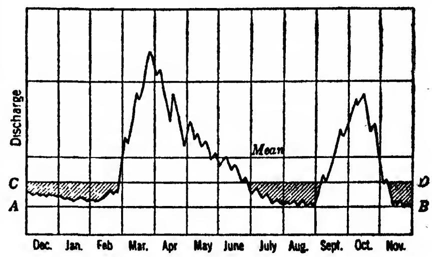

FIG. 1. Hydrograph.

Collection and storage practices at a number of large plants are described below:

The NEVADA CONSOLIDATED COPPER Co., in connection with its central reservoir on Duck Creek (*109 J 857*), laid 54,800 ft. of feeder lines to convey water from four tributary streams and thereby maintain their flow during the winter. Of this total, 45,000 ft. (at three tributaries) consisted of 8- and 12-in. riveted, slip-jointed, light-weight pipe in 20-ft. sections, made in the company's shop at a cost of 7¢ per lb., and asphalted. The lines were laid so as to develop little pressure. Joints were made by warming the larger end to expand it and soften the asphalt; the small end of the next section was then driven in by a ram supported on a light tripod. Three men laid 1,500 to 2,000 ft. of 8-in. pipe in this manner per day. The total cost of these three lines was 62¢ per ft. for the 8-in. and 75¢ per ft. for the 12-in. line. The fourth line, 9,800 ft. of 6-in. pipe designed to carry 150 lb. per sq. in., cost $1.53 per ft.

NEVADA CONSOLIDATED COPPER Co., just below its main gravity storage dam on Duck Creek, drove a tunnel 1,150 ft. long across the valley at the bottom of gravelly soil, 40 ft. deep, resting on hardpan. This intercepted 2 cu. ft. per sec. of the seepage from the reservoir, which was raised by a hydraulic ejector operated by a high-pressure gravity line. McGill Springs, at the Nevada Consolidated smelter, deliver 9 to 12 cu. ft. per sec. This was formerly pumped to mill-supply tanks by two motor-driven centrifugal pumps, each with capacity of 4.9 cu. ft. per sec., at cost of 0.77 to 1.04¢ per ton of water. One triple-expansion steam pump, with maximum capacity of 12 cu. ft. per sec. against 480-ft. head did the work at about half the cost of the electric installation (*109 J 857*). NEW CORNELIA'S water comes from a 2-compartment shaft 600 ft. deep, sunk for the purpose at a point 8 mi. northeast of Ajo. A duplex, double-acting pump, direct-connected to a synchronous motor, delivers 800,000 to 1,000,000 gal. per day through 6.7 mi. of 10-in. iron pipe against a total head (including friction) of 1,375 ft. (*60 A 22*). The 2,000-ton ALLENBY mill of the GRANBY CONSOLIDATED, requiring 4.6 tons of water per ton of ore, is supplied from the Similkameen River, one mile away, by three centrifugal pumps (one in reserve) which have a capacity of 800 gal. per min. each, discharging through 5,000 ft. of 14-in. pipe against 600-ft. static head (*115 J 989*). At ALASKA-JUNEAU salt water was pumped from Gastineau channel, with two centrifugal pumps, 3,000 gal. per min. each; each pump direct-connected to a 400-hp. squirrel-cage induction motor (*120 P 251*). At ALASKA-GASTINEAU, treating 10,000 tons a day with 5.2 tons water per ton ore, there is sufficient gravity supply for five summer months; the remaining months salt water is pumped with three 2-stage Byron Jackson turbines of 1,000-, 2,000-, and 3,000-gal. per min. capacity respectively against a head of 275 ft., with the expenditure of 700 hp. (*63 A 488*). Water for the CHINO MILL, Hurley, N. M., is obtained from wells and streams, respectively 5 mi. south, 1 mi. northeast, 4 mi. and 5 mi. west, the last two using the same steel pipe line. The pump stations are equipped with Aldrich electric-driven pumps (*104 P 464*). Storage at Hurley is 3,000,000 gal. New water amounts to 18% of the 7.1 tons in circulation per ton of ore.

At the 4,000-ton PANDA concentrator at Katanga water is pumped from the river, 2 mi. distant, by two 3-stage centrifugal pumps, each of 3,300 gal. per min. capacity and each direct-connected to a 525-hp. synchronous motor. The pumps deliver through 24-, 26-, and 28-in. spiral-riveted pipe against 300 ft. head. After passing through the powerhouse condensers, the water is elevated another 200 ft. by three 2-stage pumps, each driven by 350-hp. synchronous motors. The capacity of the two mill reservoirs is 3,820,000 gal. (*29 MM 137*).

INSPIRATION, treating 14,700 tons ore per day (1924) obtained its daily supply of 6,700,000 gal. (1.89 tons per ton of ore) of new water from six wells, 300 ft. to 1,400 ft. deep in gravel, at a point 14,500 ft. from the mill (*G. H. Ruggles, PC*). Well pumps deliver through 1,000 ft. of 10-in pipe against a static head of 80 ft. to the station pumps operating against a static head of 520 ft. and delivering to a 3,000,000-gal. mill reservoir through a 20-in. pipe line. The line is partly of steel with leaded bell-and-spigot joints, partly of flanged pipe. Power requirements are 3.49 kw.-hr. per 1,000 gal. The approximate total cost is 5¢ per 1,000 gal. (=2.2¢ per ton of ore). For recovery of old water see Art. 3.

At the RAY CONSOLIDATED mill, Hayden, Ariz., treating 10,000 tons of ore per day, 35,000 tons of water per day is pumped from wells near the Gila River through 9,000 ft. of 26-in. wood-stave pipe against head of 310 ft. (*W. S. Boyd, PC*). The initial cost of the water plant was $400,000. Power for pumping is 1.3 kw.-hr. per 1,000 gal. (1.09 kw.-hr. per ton of ore) showing an over-all efficiency of 75%; the total cost of water is 3.4¢ per 1,000 gal. (2.85¢ per ton of ore). No provision for recovery of water has been found necessary. The water circulation in the gravity section of the mill (jigs, tables, vanners) was 6 tons per ton of ore.

At MIAMI, treating 7,000 tons of ore a day with an average water circulation of 3.5 tons per ton of ore, 1,600 gal. of new water per min. (1.4 tons per ton of ore) is pumped from wells and mine shafts 4 mi.

away, against a total head of 862 ft. with an expenditure of 3.5 kw.-hr. per 1,000 gal. at a cost of 7¢ per 1,000 gal. (2.3¢ per ton of ore). Old water to the amount of 2,500 gal. per min. (2.1 tons per ton of ore) is reclaimed from the tailing dam, against head of 160 ft., with an expenditure of 235 hp. and at cost of 1.5¢ per ton of ore. (For methods of reclaiming, see Art. 3.) In 1922 Miami spent 4.6¢ per ton of ore for mill water, or 7.1% of the total cost of milling.

Chemical composition of mill water may be important, especially when mine water is to be used. Mechanical troubles may be caused by the corrosion of metal by acid water, or by lime accretions deposited by hard water. Flotation is highly susceptible to variation in character of the water, with respect both to its soluble and its suspended matter, and certain special flotation methods require careful control of the character of water entering the mill.

In SOUTHEAST MISSOURI it is common practice to use mine water as far as it goes, supplemented by pumping stations on Big River and Flat River The water in circulation averages 7 to 11 tons per ton of ore, and a 3,000- to 4,000-ton mill can usually operate with a supply of new water amounting to 700 gal. per min. (4,200 tons per day), the principal loss occurring with flotation tailing. The mine water often carries as much as 30 grains of calcium and magnesium salts per gal., and the piping, launders, and tables of the mills require frequent cleaning (*57 A 322*). At TUL MI CHUNG mill, Korea, concentrating a highly complex sulphide ore exclusively by flotation (*33 I M M 2*), water is obtained by pumping from a reservoir fed by a stream which, during 9 months of the year, carries a large proportion of suspended clay in addition to dissolved salts corresponding to 44 parts total CaO and 12 parts MgO per million. Coagulation is effected by adding 300 lb. of lime to the 1,700 tons of water consumed per day (0.18 lb. lime per ton) followed by settling before pumping. Undissolved lime is injurious to flotation of this ore, but free alkalinity of 0.0004% CaO is helpful. Lime is not added during the 3 months that the water is clear.

At CONSOLIDATED COPPERMINES milk of lime was added to the discharged tailing just before it entered the final Dorr thickener, in order to overcome interference with flotation caused by sulphuric acid and iron salts. All mine water used in the mill was first sent to the same thickener, which was thereby made to act as a water-treatment plant, the overflow being returned to the main supply tank, while precipitated calcium sulphate and iron hydroxides were discharged with the thickened tailings. By a similar arrangement of flow at the UTAH CONSOLIDATED mill, constant character of mill water was maintained, although chemical treatment was not required. At the UTAH APEX mill, acid salts in the mine-water supply were neutralized, and at the same time a desirable flotation reagent was introduced, by adding sodium sulphide at the fine-crushing mills and combining the flotation tailing and new mine water in the same Dorr tank, the overflow of which returned to the storage supply, while the thickened tailing, carrying also the precipitated impurities from the mine water, passed over concentrating tables and thence to waste.

Water conservation may be necessary or advisable: (*a*) where new water is scarce or expensive; (*b*) to save cost in pumping new water, where the escaping water can be collected at an elevation above that of its original source; (*c*) to avoid stream pollution; (*d*) as an incident to impounding tailing.

The most notable examples of systematic conservation in the United States are found among the lead-ore concentrating mills of SOUTHEAST MISSOURI, which recover 80 to 90% of the mill water; the zinc mills of the JOPLIN DISTRICT, and the copper-flotation mills of the SOUTHWEST, whose average return of water ranges from 70 to 85%. The STA. BARBARA lead-carbonate concentrator in Mexico returns over 90% of its circulating mill water. (See Table 14.)

A tailing pond is the most common means for water recovery, sometimes in combination with mechanical devices, but frequently alone. For methods of forming retaining dams, see Art. 3. Water is clarified by natural sedimentation, or by discharging the slime portion of the tailing on top of a growing pile of sand tailing, which acts as a filter (*57 A 332, 420*). This latter method was formerly the usual practice in SOUTHEAST MISSOURI, but is now largely abandoned in favor of settling ponds.

Mechanical dewaterers, designed primarily for dewatering concentrate, sand tailing, etc., but incidentally yielding an overflow sufficiently clear to be returned to the mill circuit, can often be so placed as to afford considerable economy in returning water to the central supply tank. Devices of this type include the Allen, Boylan, Callow, Caldecott, and similar settling cones, the Akins, Dorr, Esperanza, and other varieties of screw or scraper dewaterers, and Dorr settling tanks of the smaller sizes. Filter water is also suitable for returning. If not wanted where it can be immediately conducted by gravity, the clear water can be returned to the main supply system by pumps discharging directly into the main water pipes in the mill, thereby avoiding a separate column pipe from each pump to the main pressure tank.

Clarifying tanks, for the primary purpose of reclaiming water and discharging thickened slime, are now commonly of the Dorr type, having the advantage of large capacity with small loss of mill height. Tanks of the larger sizes, 50 to 200-ft. diam., are frequently placed outdoors (except in cold climates) set with the bottom below the general level of the ground.

HYDRAULICS

[THE MATERIAL FROM THIS POINT TO THE END OF ART. 2 IS CONDENSED FROM SEC. 27, FIRST EDITION, AS WRITTEN BY CHAS. T. PORTER]

Dams. Unit pressure at distance h below the surface in a body of still water is $p = wh$ where w = weight of a cubic unit of water and h = depth below the surface, called HEAD. Pressure per sq. ft. is $p = 62.5h$. TOTAL NORMAL PRESSURE on any submerged area is $p_n = wAh_0$, where A = total area in sq. ft. and h_0 = the vertical distance from the surface to the center of gravity of the area in ft. In the case of a VERTICAL DAM of height $= h$, the area per lin. ft. is h and $h_0 = h/2$, hence $p_n = wh^2/2$. PRESSURE IN A GIVEN DIRECTION is $p_1 = p_n \cos\theta = wA_1h_0$, where θ is the angle between the given direction and the normal and A_1 is the projection of the submerged surface on a plane normal to the given direction. CENTER OF PRESSURE of a submerged surface is the point of application of the resultant pressure.

For a RECTANGLE with the top in the liquid surface, the depth of the center of pressure is $^2/_3h$. For submerged rectangles the total pressures and centers of pressure may be found by constructing pressure diagrams (Fig. 2). The area of the diagram represents total pressure and the c.g. of the diagram is opposite the center of pressure. A general rule for location of the center of pressure is: $y_p = I/S$, where I is moment of inertia of the area, S is the moment of the area (= area × distance of c.g. from the axis), and y_p is the arm of the center of pressure, all with respect to an axis which is the intersection of the plane of the submerged surface with the water level. A more convenient form is $y_p = y_0 + k_0^2/y_0$, where y_0 is the distance from the axis to the c.g. and k_0 is the radius of gyration of the submerged area about its c.g. The distance k_0^2/y_0 becomes negligible when the head exceeds three or four times the vertical dimensions of the submerged surface.

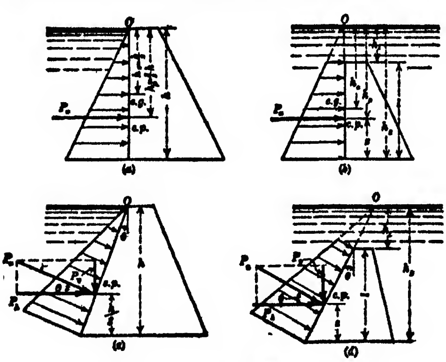

FIG. 2. Hydraulic pressure diagrams.

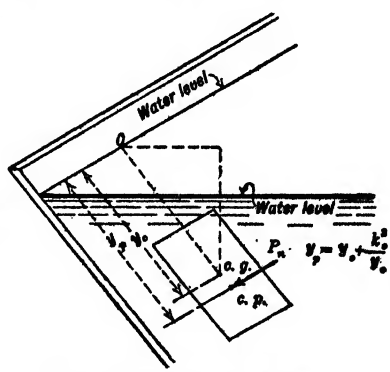

FIG. 3. Sketch for Example 1.

Example 1. A square gate, 2 × 2 ft., inclined 60° from the horizontal, with its c.g. 5 ft. below the surface, covers a rectangular opening (Fig. 3). The gate is hinged at the upper edge and it is required to find the moment about the hinge necessary to open the gate.

$p_n = wAh_0 = 62.5 \times 4 \times 5 = 1{,}250$ lb. $y_0 = 5 \sec 60° = 5.77$ ft. $y_p = 5.77 + 0.333/5.77 = 5.828$ ft. Moment about hinge $= 1{,}250 \times 1.05 = 1{,}320$ lb.-ft.

Example 2. A vertical wall has 15 ft. of water on one side and 6 ft. on the other. Find the overturning moment on the wall per lin. ft.

$p_1 = 62.5 \times 15^2/2 = 7{,}040$ lb. $p_2 = 62.5 \times 6^2/2 = 1{,}125$ lb. $M = 7{,}040 \times 15/3 - 1{,}125 \times 6/3 = 32{,}950$ lb.-ft.

Percolation. If water percolates under a rectangular masonry dam in such a way that full hydrostatic pressure is developed, the upward pressure of water decreases the stability against overturning as though the unit weight of the masonry were decreased 62.5 lb. per cu. ft. Such percolation should be prevented by cutoff walls and drains.

Pressure on gates and tanks. Resultant pressure on a submerged gate is due to the difference of head h on the two sides and is of uniform intensity over the whole of the submerged surface. Pressure $p = wAh$; the intensity is constant and the center of pressure and c.g. coincide.

Unit tensile stress in a pipe or circular tank is given by the formula for HOOP TENSION, $Pd = 2St$, where P is internal pressure in lb. per sq. in., d is diameter in inches, t is thickness of shell, and S is the unit stress in lb. per sq. in. The lower limit of applicability is $d = 30t$; the expression applies to pipes, steel tanks, steel bands for wood-stave pipe and steel for reinforced concrete tanks.

Example. A standpipe 60 ft. high and 30 ft. diameter is to be built of riveted steel plates, the efficiency of the joints being 70% and allowable stress 10,000 lb. per sq. in.

Divide the pipe into any number of sections (say five) and design each section for the internal pressure at its lower edge. For the lowest section, $P = 0.434 \times 60 = 26.04$; therefore $26.04 \times 360 = 2 \times 10{,}000 \times t \times 0.70$, and $t = 0.67$ in. or $^3/_4$-in. plates. The other sections would be made of $^1/_2$-, $^3/_8$-, and $^1/_4$-in. plates respectively. The same principle of division applies to spacing steel bands on wood-stave tanks and reinforcing bars in concrete tanks.

Transport of water from source or storage to the point of consumption is effected either in open channels or in some form of pipe. Flow through such channels is in accord with certain theoretical laws, modified by friction losses, as follows.

Torricelli's theorem. The velocity v of flow of a jet discharging under a head of h ft. is the same as the velocity acquired by a body falling freely through the height h, thus $v = \sqrt{2gh}$.

Bernouilli's theorem. For steady frictionless flow the sum of the pressure head and the velocity head equals the hydrostatic head that obtains when there is no flow. For actual conditions involving friction, the sum of the pressure head, velocity head, and elevation head above some assumed datum plane at some station 1 equals the sum of the corresponding heads at any other station 2, plus FRICTION HEAD h_f if 2 is downstream, and minus if upstream. If $h = p/w$ = pressure head, and z = elevation head above the assumed datum plane, $h_1 + z_1 + v_1^2/2g = h_2 + z_2 + v_2^2/2g + h_f$.

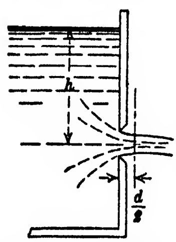

FIG. 4. Standard orifice.

Flow from orifices. Discharge from a standard orifice of diameter d (Fig. 4) contracts, at a distance $d/2$ from the plane of the orifice, to an area that is 62% of that orifice, at which point pressure head becomes zero and velocity attains substantially the value $v = \sqrt{2gh}$. The ratio of contracted area to area of orifice is C' = the COEFFICIENT OF CONTRACTION. Actual velocity is given by $v = C_1\sqrt{2gh}$ where C_1 is COEFFICIENT OF VELOCITY. Discharge is the product of velocity and area of the contracted jet and is

$$q = C'C_1A\sqrt{2gh} = CA\sqrt{2gh}$$

where C is the COEFFICIENT OF DISCHARGE and A is the area of the orifice.

Standard orifice gives an accurate measure of the flow of water. Its center should be at least $3d$ from the sides and bottom of the tank; the edges should be sharp. For SMALL ORIFICES, 1 in. or less in diameter, C may be taken as 0.61 for circular and 0.62 for square orifices. FOR LARGER ORIFICES and HIGH HEADS the average value of $C = 0.597$ for circular orifices and 0.604 for square orifices may be used. Error of less than 3% may be expected. If greater accuracy is desired, the orifice should be calibrated; whereupon an error less than 1% may be obtained.

Large orifices under low heads. For a rectangular orifice of breadth b: $q = {}^2/_3C\sqrt{2g}\cdot b(h_2^{3/2} - h_1^{3/2})$ where h_1 and h_2 are the heads on the top and bottom of the orifice respectively, and the head on the center of gravity of the orifice ($h_{c.g.}$) is less than three times the depth of the orifice.

Submerged orifices. Discharge is slightly less than into the atmosphere; the difference is negligible for large orifices; for orifices 1 in. in diameter or less it may be 2%. The value of $C = 0.60$ is in general use.

Velocity of approach to an orifice adds velocity head $h_v = v^2_a/2g$, where v_a = such velocity, and EFFECTIVE HEAD is $H = h + v^2_a/2g$. Then $q = CA\sqrt{2gH}$. If the approach channel and the orifice have areas a and A respectively,

$$v = C_1\sqrt{\frac{2gh}{1 - C^2\left(\frac{A}{a}\right)^2}}; \quad q = A\sqrt{\frac{2gh}{\left(\frac{1}{C}\right)^2 - \left(\frac{A}{a}\right)^2}}$$

and for a RECTANGULAR ORIFICE under low heads,

$$q = {}^2/_3C\sqrt{2g}\cdot b[(h_2 + h_v)^{3/2} - (h_1 + h_v)^{3/2}]$$

Suppression of contraction is effected by an internal projection at the perimeter of the orifice. Suppression increases discharge. For a square orifice with one side suppressed the increase is about 3.5%; two sides, 7.5%. For rectangles with the lower edge suppressed the increase is 6 to 7%, if $b = 4d$, and 8 to 12%, if $b = 20d$. Avoid suppressed orifices for accurate work.

Discharge under a falling head. If Y is area enclosed by the water line when the head on an orifice is y, the time for the head to fall from H to h is

$$t = \int_h^H \frac{Yy^{-1/2}}{CA\sqrt{2g}}\,dy$$

where Y is, in general, some function of y. If the cross section is constant and equal to a, the time to empty a vessel is $t = 2a\sqrt{H}/CA\sqrt{2g}$, which is twice that required to discharge a similar amount under a constant head H.

The miner's inch is a unit of flow used in mining and irrigating work; it is rapidly becoming obsolete. It is defined as the discharge from an orifice one inch square under a head on its center of 6.5 in. The value of this unit and its definition vary in different states. The legal equivalent in California is 40 miner's inches = 1 cu. ft. per sec., in Colorado 38.4, while in Arizona, Idaho, Nevada, and Utah, the value is 50, by common agreement.

Flow under pressure. When water in a closed vessel is under unit pressure p in addition to its own weight, the velocity and discharge from an orifice are found by computing the equivalent head in feet, $H = h + p/w$. If discharge takes place into a vessel in which the unit pressure is p_0, the equivalent head is $H = h + p/w - p_0/w$.

Example. A 1-in. circular orifice under a head of 10 ft. and an additional pressure of 10 lb. per sq. in. discharges into a 26-in. vacuum and it is desired to find the discharge.

The 26-in. vacuum is equivalent to a negative head of $26 \times 34/30 = 29.5$ ft., which increases the effective head, hence $H = 10 + 10 \times 2.304 + 29.5 = 62.5$ ft. $q = CA\sqrt{2gH} = 0.61 \times 0.00546\sqrt{64.4 \times 62.5} = 0.212$ cu. ft. per sec.

Short tubes of length 2 to 3 diameters are treated as orifices. LONG TUBES are classified as pipes. Addition of a short tube to an orifice decreases velocity but increases discharge, although friction losses are increased, because the jet after contraction re-expands to fill the tube. Fig. 5 shows common types of tubes and end connections.

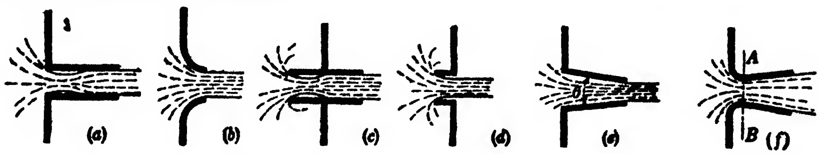

FIG. 5. Short tubes and mouthpieces.

Item (*a*) is the STANDARD SHORT TUBE for which $C' = 1.0$, $C_1 = C = 0.82$, provided the jet re-expands to fill the tube. For high heads the discharge may jump clear of tube, when the device becomes a standard orifice with $C = 0.61$. (*b*) is a ROUNDED ORIFICE which has a coefficient of discharge varying from 0.61 to 0.99 depending upon the curvature. Even slight dulling of the edge of a standard orifice increases discharge several per cent. while if the curvature of the orifice conforms to the direction of the stream lines, the contraction is entirely suppressed and $C_1 = C = 0.96$–0.99. This is an ideal end connection to avoid energy losses. (*c*) is an inward-projecting tube for which $C_1 = C = 0.72$. It is a common type of end connection for a pipe line when no attempt is made to avoid entrance losses. (*d*) is BORDA'S TUBE for which $C = 0.5$–0.53. (*e*) is a conical converging tube, the discharge from which varies with the value of the angle θ; the maximum value of C is 0.94, which occurs when $\theta = 13.5°$. (*f*) is a VENTURI OR COMPOUND TUBE composed of a rounded orifice and an expanding tube with angle of about 10°. Pressure at section AB is less than atmospheric and may be as low as -24 ft.; the equivalent head is $h + 24$, which gives theoretical values of $C = 8$ or 9 for section AB. Experiments by Francis show C actually to be as high as 2.43. The coefficient for the discharge end is always less than unity.

Loss of head for any pipe or orifice discharging freely with velocity v under total head h is $h_f = h - v^2/2g$. Loss of head for an orifice or tube whose coefficient of velocity is C_1 is

$$h_f = (1 - C_1^2)h = (1/C_1^2 - 1)v^2/2g.$$

Example. For a standard orifice, $h_f = 0.04h = 0.041v^2/2g = 0.11v_0^2/2g$ where v_0 is the velocity in the plane of the orifice. For a standard short tube (Fig. 5, *a*), $h_f = 0.33h = 0.49v^2/2g$. For an inward-projecting tube (Fig. 5, *c*), $h_f = 0.48h = 0.93v^2/2g$.

Nozzles. Types of nozzle tips are shown in Fig. 6. SMOOTH NOZZLE is most common. If properly designed there should be no contraction and $C_1 = C = 0.97$–0.99. The RING TIP was designed from the mistaken notion that the ring would increase velocity. The coefficient of velocity is the same as for the smooth type while the coefficient of discharge depends on the relative areas of opening and ring. For a SQUARE RING an average value is $C = 0.74$ while an UNDERCUT RING has a value somewhat less. The NEEDLE NOZZLE is designed to regulate flow by moving the needle in and out and has an efficiency of 95 to 98%; the coefficient of discharge varies from 0.82 to 0.95, being least when the nozzle is nearly closed. Expressions for the velocity and discharge through a nozzle are the same as those for an orifice with velocity of approach.

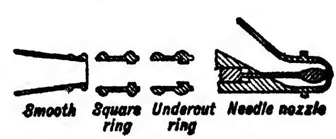

FIG. 6. Types of nozzle tips.

Discharge in gallons per minute from a nozzle D in. diameter, attached to a pipe d in. diameter, with the pressure at the base of the tip $= p$ lb. per sq. in. is

$$q = 29.83D^2\sqrt{\frac{p}{(1/C)^2 - (D/d)^4}}.$$

A standard fire stream is one flowing 250 gal. per min. through a 1 1/8-in. smooth nozzle with a pressure at the base of the tip of 45 lb. per sq. in. The hydrant pressure required to throw this stream through 50 ft. of the best rubber-lined hose is 56 lb. per sq. in.; for 200 ft., 77 lb. per sq. in. The pressure drop per 100 ft. of best-quality hose is about 14 lb. per sq. in.; for poor-quality hose it may be double this figure. The best hydrant pressure for fire service is 80 to 100 lb. per sq. in.

Power of a jet discharging W lb. per sec. is $Wv^2/2g = wAv^3/2g$ ft.-lb. per sec., where w = weight of a cu. ft. of fluid, A = cross-section of the jet in sq. ft., and v = velocity in ft. per sec. HORSEPOWER = $wAv^3/1{,}100g$. Power of a jet discharging from an orifice or nozzle (coefficient of discharge = C and coefficient of velocity = C_1) is $P = CC_1wA\sqrt{2g}\,h^{3/2}$ ft.-lb. per sec. The efficiency of such a jet is $E = C_1^2$.

Example. The respective powers of a standard orifice and standard short tube are $0.58wA\sqrt{2g}\,h^{3/2}$ and $0.55wA\sqrt{2g}\,h^{3/2}$. Corresponding efficiencies are 96% and 67% respectively.

Impulse of a jet in a given direction in pounds is W/g × *change of velocity in that direction*, in which W = lb. of water deflected per sec. If the jet impinges on a flat plate (Fig. 7, a), the impulse is Wv/g lb.; if direction is reversed without loss in friction (Fig. 7, b) the impulse is $2Wv/g$; while for a curved vane (Fig. 7, c) the impulse in the original direction of jet is $Wv(1 - \cos\theta)/g$. If a jet discharging W lb. per sec. strikes a flat plate moving in the direction of the jet with velocity u, the water that strikes the plate per sec. is $W(v - u)/v$ and the impulse in direction of motion is $W(v - u)^2/vg$. If the jet strikes a series of flat vanes so that all the water discharged strikes some vane, the impulse is $W(v - u)/g$.

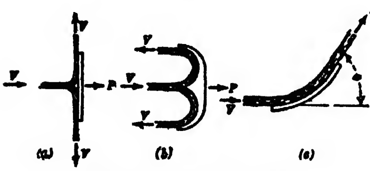

FIG. 7. Impinging jets.

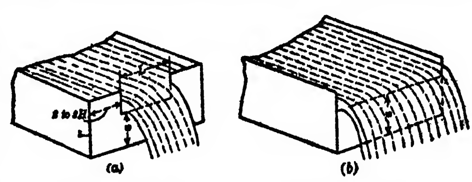
Reaction of a jet issuing from the side of a vessel is $R = Wv/g = wAv^2/g = 2wAh$, in which w = weight per cu. ft. of the fluid, A = cross-section of the jet in sq. ft., and h = head on orifice in ft. The reaction is equal to the impulse of the jet on a flat plate and is twice the hydrostatic head. If the jet issues from a standard orifice with coefficient of velocity 0.98 and coefficient of contraction = 0.62, the reaction of the jet on the containing vessel is $R = 1.22wAh$.

A weir is a dam or obstruction placed in an open channel, over which water is caused to flow, or a notch in the side of a vessel through which water flows. If the top or CREST of the weir is a thin plate with a sharp edge, flow is analogous to that through a rectangular orifice with head on the upper edge = zero. If the weir is a rectangular notch with ends $3H$ or more from the walls of the approaching channel, full contraction of the stream is developed and the device is known as a CONTRACTED WEIR (Fig. 8, a). If the length of the weir is the same as that of the approaching channel, so that no contraction takes place at the ends, the weir is called a SUPPRESSED WEIR (Fig. 8, b).



Contracted weir. Suppressed weir.

FIG. 8. Weirs.

Discharge from a weir. The theoretical discharge is $Q = {}^2/_3\sqrt{2g}\,LH$, and the actual, $Q = {}^2/_3C\sqrt{2g}\,LH^{3/2}$, in which H is the height above the crest of the weir to the level of still water, L is the length of crest over which water is flowing, and C is a constant which varies slightly with the type of weir and head but has an approximate value of 0.62.

Velocity of approach. It is not always possible to measure the head H to the level of still water on account of velocity in the approaching channel. Mean velocity of approach v_a is found by dividing the discharge by the cross-section of the approach channel and the corresponding velocity head $h_v = v_a^2/2g$. The observed head H must be increased by some function of the velocity head, giving the general form

$$Q = {}^2/_3C\sqrt{2g}\,L(H + nh_v)^{3/2}$$

in which n varies from 1.00 to 2.00 depending on the ratio of head to height of crest above the bottom and on the ratio of mean velocity of approach to surface velocity.

Francis formulas for SUPPRESSED WEIRS are $Q = 3.33LH^{3/2}$ and $Q = 3.33[(H + h_v)^{3/2} - h^{3/2}]$. Later investigators prefer the form $Q = 3.33L(H + 1.4h)^{3/2}$.

For CONTRACTED WEIRS Francis decreased the length L by $0.1H$ for each end contraction, making the expression for the ordinary rectangular notch

$$Q = 3.33(L - 0.24)(H + 1.4h)^{3/2}$$

These formulas are widely used and should give results within 1 to 3% for carefully constructed SUPPRESSED WEIRS with heads from 0.3 to 2.0 ft.; for $H = 0.2$, increase the discharge 3%; and for $H = 0.1$, increase 7%. If the height of crest a exceeds $4H$, the influence of velocity of approach will cause increase in discharge of 1% or less, which is negligible in view of other uncertainties. For CONTRACTED WEIRS, which are a little less accurate, velocity of approach is negligible unless the ratio of H to a is abnormally high.

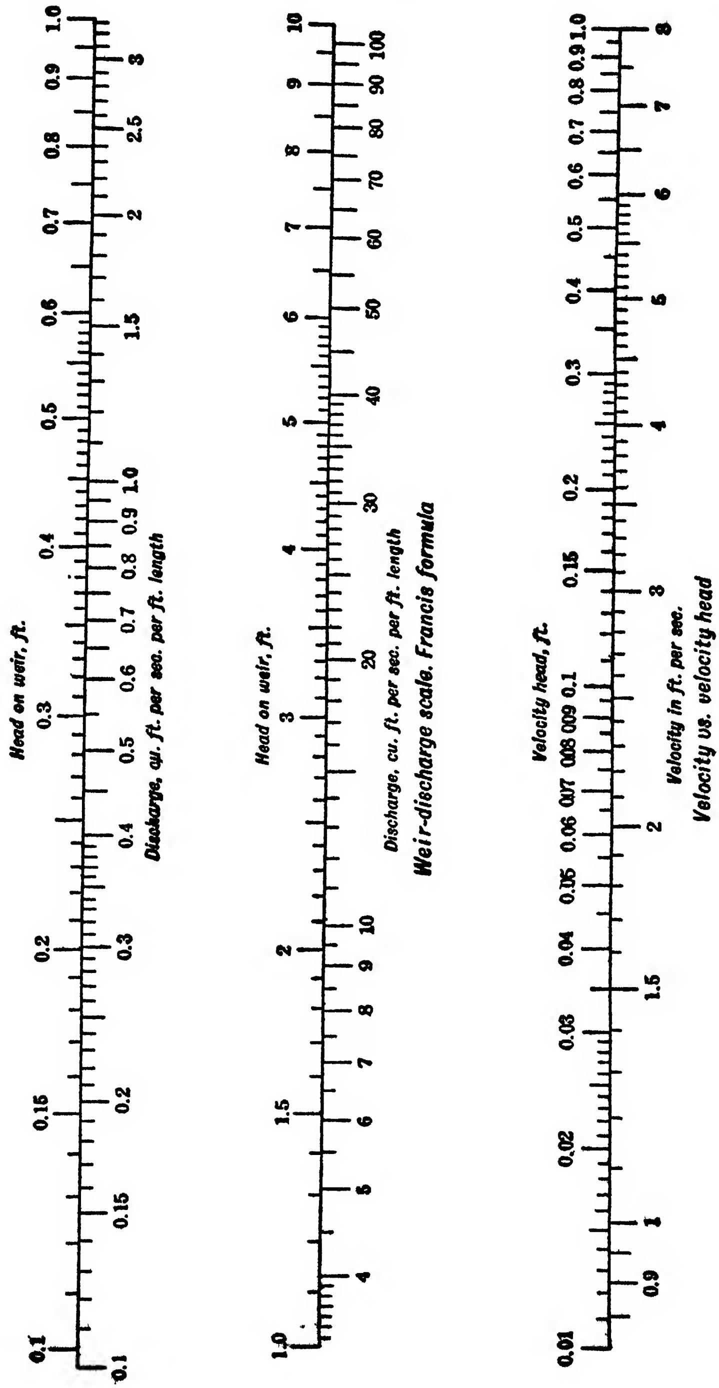


FIG 9. Scales for weir calculations.

Fig. 9 gives the discharge in cu. ft. per sec. per ft. of length by the Francis formula. To use the scale, find first the approximate discharge, neglecting velocity of approach. Divide this by the area of the approaching channel to get v. Replace H by $H + 1.4v^2/2g$, taking the value of the velocity head from Fig. 9. For CONTRACTED WEIRS replace L by $L - 0.2H$.

Example 1. Find the discharge from a SUPPRESSED WEIR 4 ft. long under a head of 0.625 ft.; crest 2 ft. above the bottom of the channel.

From Fig. 9, the discharge per ft. of length is 1.65; hence $Q = 6.60$. The area of the channel is $4 \times 2.625 = 10.5$ sq. ft., hence $v_a = 0.628$ ft. per sec. and $h_v = 0.0061$. Then $H = 0.625 + 1.4 \times 0.0061 = 0.6335$ and $Q = 6.72$ cu. ft. per sec.

Example 2. A CONTRACTED WEIR is to be designed to discharge 4 cu. ft. per sec.

Either the length or the head may be assumed for purposes of trial. Assuming $H = 0.5$, the discharge per foot of width is 1.18 and the necessary width is $4/1.18 = 3.4$. Adding $0.2H$ for the effect of end contractions the width is 3.5 ft., which lies between $4H$ and $8H$ and hence is satisfactory. End contractions should have a minimum value of 1 ft. each, making the width of channel 5.5 ft. The depth of crest should not be less than 1.5 ft., making the area of the approach channel 11 sq. ft.; velocity of approach, 0.364; and velocity head $h_v = 0.0019$, which is negligible.

Bazin formula. $Q = m\sqrt{2g}\,LH^{3/2}$, where $m = (0.405 - 0.00984 - H)\ [1 - 0.55(H/A - H)^2]$ in which a is the height of the crest above the bottom of the approaching channel. This formula needs no correction for velocity of approach and is probably the most accurate for a wide range of heads. It may be used safely for heads between 0.2 and 6.0 ft. For extremely low heads it gives high results.

Measurement of flow by weirs is the standard method for moderate flows. For correct results, the crest must be level and have sharp or square edges; the sheet of water or NAPPE must jump free of the downstream face and allow free access of air to the under side. In SUPPRESSED WEIRS the channel walls should extend beyond the crest to prevent lateral expansion of the nappe. If END CONTRACTIONS are used they should be at least $2H$ and preferably $3H$ or more in length to develop full contraction, and the height of crest a (Fig. 8) should be at least, $3H$. It is preferable that the length L be between $4H$ and $8H$, although weirs of 20 ft. or more in length are in common use. The velocity of approach should be low. For a CONTRACTED WEIR the area of the approach channel should be $6LH$ or more, which makes the velocity of approach negligible. HEAD should be measured accurately a distance more than $6H$ upstream to eliminate the slope of the surface toward the weir. For approximate work a stake is driven into the channel above the weir with its top level with the crest, and head is measured directly by a scale held upon this stake. For more accurate work water is led from the channel to a pail upon which a hook gage is mounted.

Triangular-notch weirs are convenient for measurement of very small to moderate discharges and give good results for heads between 3 and 10 in. DISCHARGE is $Q = \frac{4}{15}c\sqrt{2g}\,LH^{3/2}$, where L is width of notch H ft. above the vertex; $c = 0.60$ for angles at vertex of 90° and 60°. For a 90° weir $L = 2H$ and $Q = 2.53H^{5/2}$ cu. ft. per sec.

Trapezoidal or Cippoletti weir is designed with end slopes of one horizontal to four vertical, which will just compensate for the effect of end contractions. DISCHARGE is then given by the Francis formula $Q = 3.33LH^{3/2}$. Some authorities give $Q = 3.36/LH^{3/2}$.

ROUNDING OF CREST suppresses contraction and increases discharge. INCLINING UPSTREAM FACE with the current increases discharge while sloping the face upstream causes decrease. WIDENING THE CREST so that the nappe no longer jumps free increases friction and reduces discharge.

Dams and spillways may be regarded as weirs; they are by no means accurate as measuring devices. The coefficient in the Francis formula varies from 2.6 to 4.0 or more depending on the form of dam. For a wide flat-topped dam with width of crest greater than H the coefficient is 2.64, giving discharge 80% of standard. Rounding the crest to conform to stream lines and inclining the upstream face with the current gives a coefficient of 4.0 or more. For such a dam the discharge varies from 97 to 120% of standard as the head varies from 0.5 to 4 ft. In designing a waste weir or spillway, the probable flood discharge should be estimated, a large factor of safety introduced, and the dimensions of the weir determined from $Q = MLH^{3/2}$. A common value of M is 3.0.

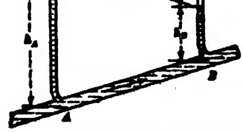

FIG. 10. Hydraulic gradient for pump-delivery pipe.

Flow in pipes. When water flows in a pipe under pressure there is a continuous loss of pressure head due to friction between the water and the pipe, and internal friction in the water. This condition is shown by Fig. 10, which shows pressure heads necessary in pumping water from A to B. Friction head h_f varies widely with the nature and condition of pipe, diameter, and velocity of flow. Many formulas have been proposed, but even for carefully laid new pipe a discharge within 10% of calculated value is all that may be expected. After a few months friction may increase as much as 20% and in the course of years the diameter may be reduced 50% by rust; this deposit forms more rapidly in some waters than others so that each case is a special problem. Friction factors are given for both new and old pipes and in pipe diagrams allowances are made for decrease of capacity with age.

Secondary losses of head are negligible in long pipes but may be a large part of the total loss in pipes of length $50d$ to $500d$. LOSS AT ENTRANCE $= mv^2/2g$ where $m = 1/C_1^2 - 1$, in which C_1 is the

coefficient of velocity for end connection; $m = 1.0$ for inward projecting pipes, 0.5 for square-edged entry with end of pipe flush with the inside of the reservoir wall, and 0 for rounded edge conforming to stream-line flow. Loss due to 90° bends is the same as that for straight pipe of length 10 to $20d$; it is smallest when radius $= 3d$; it is greater for large pipes than for small ones, varying approximately as d. Loss due to valves is uncertain but equivalent to a length of $6d$ at full gate. Loss due to expansion of section occurs when water flowing in a small pipe with velocity v_1 suddenly enters a large pipe in which the velocity is v_2; this loss is $h_t = (v_1 - v_2)^2/2g$. It occurs in hydraulic machines, pipes, and channels, whenever the section of flowing water is suddenly enlarged; it can be prevented by having the increase gradual, as in the Venturi meter. Loss due to sudden contraction of section is similar to that at the entrance to square-edged pipe; it depends on the ratio of pipe diameters and has a maximum value of $0.5v^2/2g$, in which v is the velocity in the smaller pipe.

Hydraulic gradient is a line that represents the height of the pressure head at any point in a pipe line. Fig. 11 shows this line for a short horizontal pipe with square-edged entry.

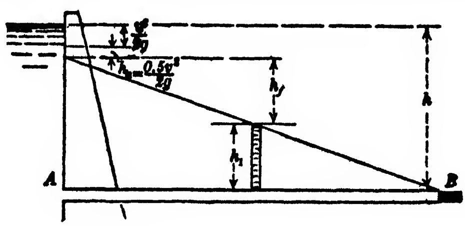

Fig. 11. Hydraulic gradient, short pipe.

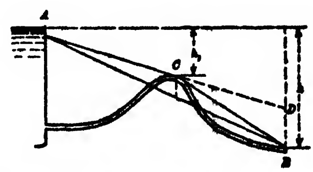

Fig. 12. Pipe above hydraulic gradient.

The pressure at any point is found from the relation: *pressure head = total head − velocity head − lost head.*

When there is no flow, the head at B is h. When free discharge occurs at B, the drop at A = the velocity head $v^2/2g$ plus entrance loss, $h_e = 0.5v^2/2g$; the head then drops uniformly to zero at B. If the pipe were laid on the hydraulic gradient there would be no pressure head and the slope would be just sufficient to give the required flow.

When a pipe rises above the hydraulic gradient (Fig. 12), negative pressure occurs at C. If this pressure is less than 25 ft., water will siphon over and discharge at B under head h. But it is almost impossible to keep the pipe air tight and air dissolved in the water is liberated under the reduced pressure; hence air collects at C and breaks the vacuum. The pipe then discharges at C under head h_1; section CB acts as a conduit running partly full. This may be avoided by closing a valve at B until the hydraulic gradient rises above C, then opening an air valve at C. Negative pressure at C may be avoided by a compound pipe that makes the hydraulic gradient ACB, Fig. 12. Fig. 13 shows the hydraulic gradient for a long compound pipe in which velocity head and secondary losses have been neglected. If the friction factor f is assumed the same for each pipe, the slope of the gradient varies as v^2/d, and since the discharge q is the same for each section, v varies as l/d^2, hence the slope varies inversely as d^5.

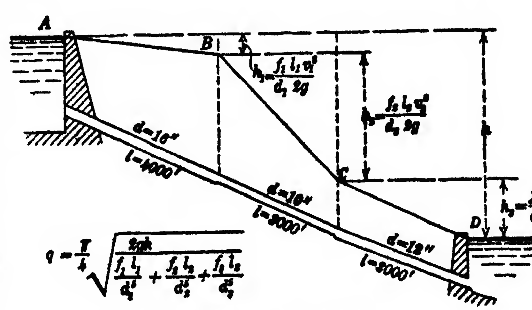

Fig. 13. Hydraulic gradient for compound pipe.

Flow in short pipes. If the loss at entrance is $mv^2/2g$ and loss due to bends, valves, and other secondary causes is $m_1v^2/2g$, then $h - v^2/2g = (m + m_1 + fl/d)v^2/2g$ and $v = \sqrt{2gh}/\sqrt{1 + m + m_1 + fl/d}$. If losses due to valves, bends, etc., are allowed for by using an equivalent length of straight pipe, the velocity and discharge for square-edged entry are

$$v = \sqrt{\frac{2gh}{1.5 + f\frac{l}{d}}} \quad \text{and} \quad q = 0.7854d^2\sqrt{\frac{2gh}{1.5 + f\frac{l}{d}}}$$

from which the diameter in feet required for discharge q is

$$d = 0.479(1.5d + fl)^{1/5}(q^2/h)^{1/5}$$

To solve the equation for diameter, use a trial value of $f = 0.02$ and omit the term $1.5d$ for the first approximation. Use a value of f from Table 17 that corresponds with the approximate value of d and solve again. For very short pipes where $l < 50d$, the coefficient m should be replaced by $1/C_1^2 - 1$ and l by $l - 3d$; hence $v = \sqrt{2gh}/\sqrt{1/C_1^2 + f(l - 3d)/d}$.

Long pipes. Where length exceeds 4,000d, secondary losses and velocity head are omitted and the formulas become

$$v = \left(\frac{2ghd}{fl}\right)^{1/2} \qquad q = 6.3\left(\frac{hd^5}{fl}\right)^{1/2} \qquad d = 0.479\left(\frac{flq^2}{h}\right)^{1/5}$$

From Darcy's experiments the friction factor $f = 0.02 + 0.00167/d$, where d is in feet, for new clean cast-iron pipe with well-laid joints, and twice this value for old, foul pipe. This value is too high for large cast-iron pipe and wood-stave pipe and too low for riveted steel pipe. Table 17 gives Merriman's values for f for new well-laid cast-iron pipe (*Treatise on Hydraulics*, John Wiley & Sons). For OLD PIPE these values should be multiplied by 2 for diameters of 3 in. or less and by 1.5 for 36 in. or more. Choice of a multiplier is a matter of judgment. To determine the diameter required for a given discharge, use a trial value of $f = 0.02$ and solve. Then select the value of f that corresponds to the first result and solve again. Pipe-flow diagrams lessen labor and are sufficiently accurate.

Example. Find the diameter required to deliver 7 cu. ft. per sec. through a pipe 5,000 ft. long under a head of 25 ft.

Table 17. Friction factors (f) for clean iron pipes

TRIAL SOLUTION: $d = 0.479(0.02 \times 5{,}000 \times 7^2 \div 25)^{1/5} = 1.37$ ft., for which $v = 4.7$. The corresponding value of $f = 0.021$, hence $d = 1.39$ ft. or 16.7 in. The commercial size selected should be 16 or 20 in.

Chezy formula is most generally used for investigation of flow in long pipes, channels, and conduits. It states that $v = C\sqrt{Rs}$, in which C is a constant, R is the hydraulic radius in ft., and s is the slope of the hydraulic gradient. The formula applies to everything from smooth pipes to turbulent streams.

HYDRAULIC RADIUS OR HYDRAULIC MEAN DEPTH is the section area of the flowing stream divided by the wetted perimeter and is expressed in feet. Velocity and discharge vary with R and are maximum for a given area when R is maximum. If p = wetted perimeter and A = section area, $R = A/p$; hence for circular conduits full or half full $R = d/4$ and for a rectangular flume b ft. wide and d ft.

deep $R = bd/(b + 2d)$. SLOPE OF HYDRAULIC GRADIENT is the friction head per unit of length; hence $s = h_f/l$. It is given as feet per 1,000 ft., ft. per mile, and as a ratio. The CHEZY CONSTANT, C, varies with R, s, and with the nature of the conduit; it is made to embrace a wide variety of conditions. See Tables 18 and 19.

Discharge of a pipe running full is given by the Chezy formula as $q = (C\pi d^2\sqrt{ds})/8$; also $d = (8q/\pi c\sqrt{s})^{2/5}$. The diameter is best found by trial using a tentative value of $C = 125$.

Relation between friction factor and Chezy constant. The Chezy formula applied to pipes under pressure is in the same form as the friction-factor formula for long pipes, $v = \sqrt{2ghd/fl}$. Replacing s by h/l and R by $d/4$, $v = C\sqrt{dh/4l}$. Equating these two values of v, there results $f = 8g/C^2$.

Pipe-flow diagrams. Fig. 14 (*U. S. Reclamation Service*) shows the relation between discharge, friction head, velocity, and diameter; if any two are known the other two may be determined.

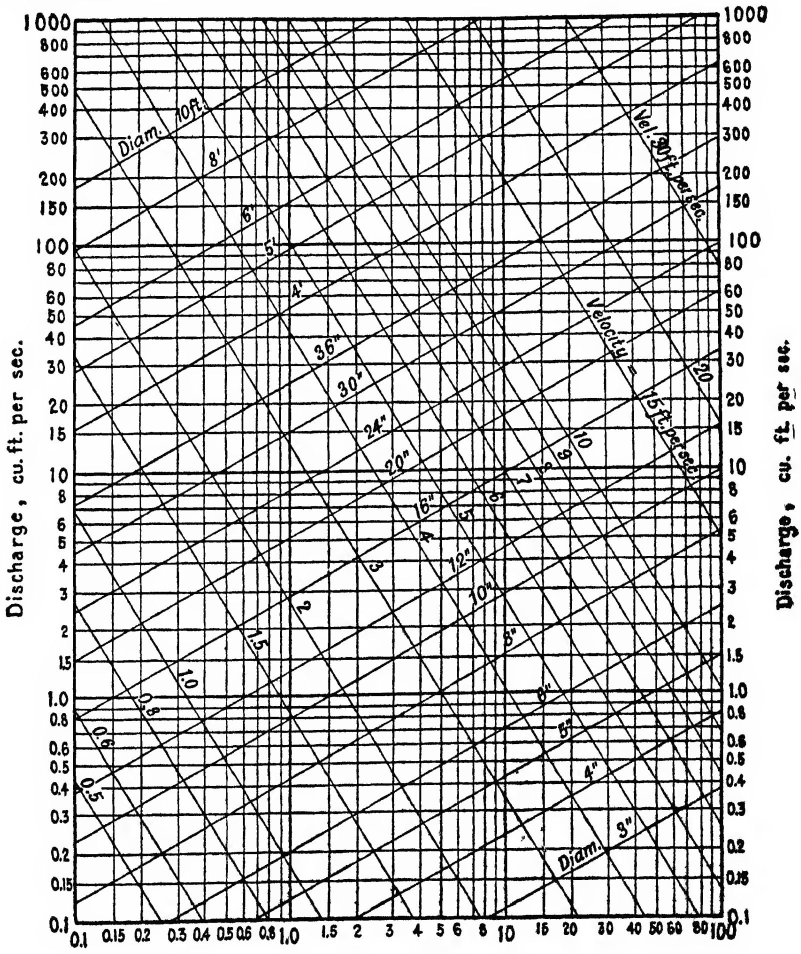

FIG. 14. Pipe flow, U. S. Reclamation Service formula.

The diagram is based on the formula $h_f = 0.38v^{1.86}/d^{1.25}$ in which h_f is friction head per 1,000 ft. of length. The constant and the exponents of v and d are based on average results of a large number of experiments; results agree quite closely with those obtained by use of Tables 18 and 19, and with

values found by Kutter's coefficient $n = 0.011$ (page 20-33). Results are for cast-iron and wrought-iron pipe in good condition; for OLD PIPE in service 10 yr. or more and for riveted-steel pipe, the friction head should be multiplied by 1.45 to 1.63 and discharge divided by 1.20 to 1.28 for velocities of 2 to 5 ft. per sec. For this case the formula is $h_f = 0.50v^2/d^{1.25}$.

Example. New pipe 2 mi. long is to discharge 10 cu. ft. per sec. with drop of head of 40 ft. What diameter is required?

$s = 40/10{,}560 = 0.00379$ or 3.79 ft. per 1,000 ft. Enter the diagram on the vertical line representing 3.79 ft. per 1,000; at intersection with the horizontal line representing 10 cu. ft. per sec. read 20-in. pipe required. If the pipe is to remain in service 10 yr. or more, divide discharge by 1.25; 20-in. pipe gives $10.8 \div 1.25 = 8.65$ cu. ft. per sec. and 24-in. pipe gives 13.6 cu. ft. per sec.

Hazen-Williams formula, $v = 1.318CR^{0.63}s^{0.54}$ is based on average results.

The constant 1.318 is introduced to make the coefficient C approximately the same as in the Chezy formula. Hazen and Williams values for C are: best cast-iron pipe, 140; good new cast-iron pipe, 130;

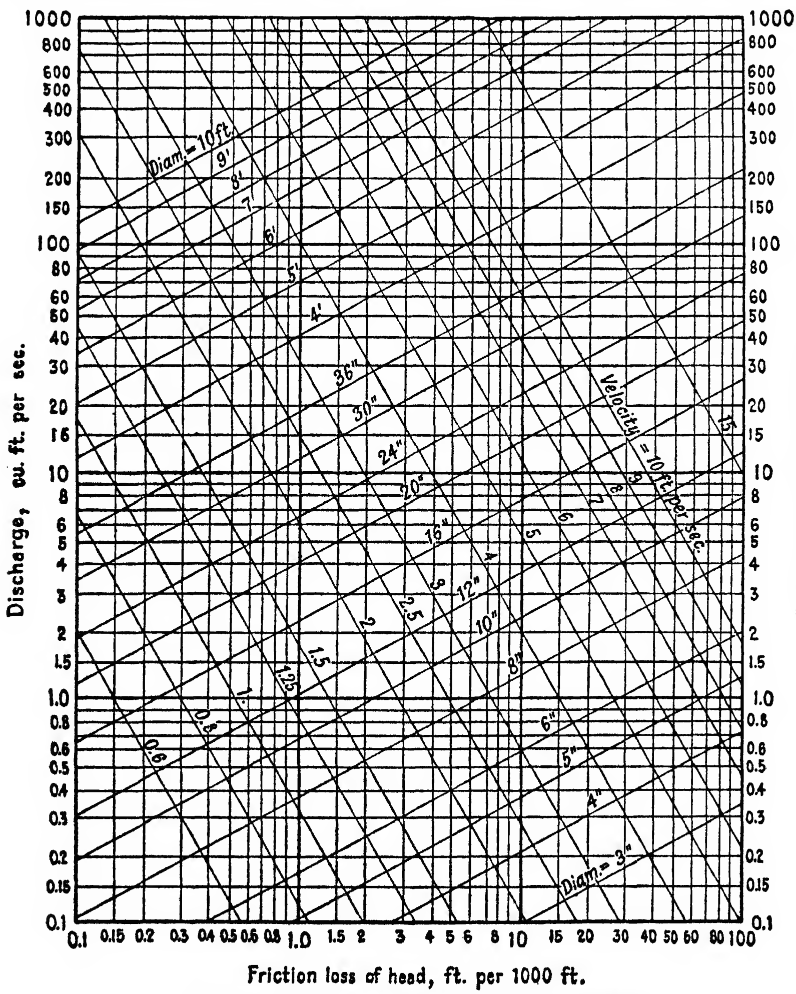

FIG. 15. Pipe flow, Hazen-Williams formula (*after Bleich*).

tuberculated pipe, 80 to 110; for DESIGN of cast-iron pipe lines, 100; new riveted-steel pipe, 110, ordinary wrought-iron pipe, 100; lead, brass, tin pipe, 140; smooth wood pipe, 120; vitrified pipe, 110; smooth clean masonry, 140; slime-coated masonry, 130; ordinary masonry, 120; brick sewers, 100. Application is much simplified by use of Fig. 15 (S. D. Bleich). The diagram is constructed for $C = 100$; for

any other value of C, multiply velocity and discharge by $c/100$. To SELECT PIPE to give discharge q, multiply q by $100/C$ giving q^1, and using this value find d from the diagram. To get ACTUAL VELOCITY, multiply the diagram value by $C/100$. For CHANNELS, multiply the hydraulic radius by 4 to get the equivalent diameter.

Example. Find the diameter of riveted-steel pipe to carry 40 cu. ft. per sec. with slope $s = 1.001$. $C = 110$. Multiply 40 by 100/110, then $q^1 = 36.36$ and $d = 46$ in. The corresponding velocity is 3.2, but since the actual discharge is 40, actual velocity is $3.2 \times 110/100 = 3.52$ ft. per sec.

Comparison of U. S. Reclamation Service and Hazen-Williams formulas. Fig. 15 is more conservative than Fig. 14, but the latter probably gives a closer indication of discharge of a pipe in fairly good condition. Hazen-Williams formula can be used for any class of pipe by choosing the proper value of C.

Compound pipe. A pipe line is to be made of sections of different diameters, the same discharge flowing through all; required to find the discharge.

Solution.

$$h = \frac{f_1 l_1 V_1^2}{2gd_1} + \frac{f_2 l_2 V_2^2}{2gd_2} + \frac{f_3 l_3 V_3^2}{2gd_3}$$

which shows that friction head for each section varies approximately as l/d^5. From this relation friction heads may be found by trial such that each section gives the same discharge. In Fig. 13 let the diameters be 16 in., 10 in., and 12 in., and the lengths 4,000 ft., 3,000 ft., and 3,000 ft., and let the total head be 120 ft. Friction heads for the sections vary as $4{,}000/16^5 : 3{,}000/10^5 : 3{,}000/12^5$, or as $3.8 : 30 : 12$. Hence the respective heads are $120 \times 3.8/45.8$, $120 \times 30/45.8$, $120 \times 12/45.8$ or 9.95 ft., 78.6 ft., and 31.4 ft. Fig. 14 shows that each section will discharge 4.4 cu. ft. per sec. under these heads.

Branching pipe. To design branching pipe (Fig. 16) to discharge given amounts at C and D assume a pressure drop from A to B and design the section A–B for a discharge equal to the sum of those required at C and D. Then design sections B–C and B–D to give the desired discharge under their respective heads. If the diameter of any section is fixed, all pressure drops are fixed and no assumptions are necessary.

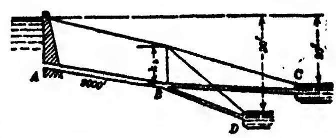

FIG. 16. Branching pipe.

Example. Find the diameters required to discharge 10 cu. ft. per sec. at C and 5 cu. ft. per sec. at D. Assuming a drop of 10 ft. from A to B, section A–B must discharge 15 cu. ft. per sec. under 10 ft. head or 5 ft. per 1,000 ft. From Fig. 14, d lies between 20 and 24 in. Assuming the latter, the drop is 6 ft., leaving heads on C and D of 14 and 24 ft. respectively. B–C is then between 16 and 20 in., and B–D between 10 and 12 in. It is best to select the larger diameters and control the discharge by gate valves.

To find the discharge from an existing pipe line, make a series of trials assuming different drops from A to B until one is found that gives a flow through A–B that equals the sum of those through B–C and B–D. If, in Fig. 16, the diameter of A–B is 30 in., B–C 24 in., and B–D 16 in., assuming 10-ft. drop from A to B, the discharges are: A–B, 33 cu. ft. per sec.; B–C, 20; and B–D, 14.

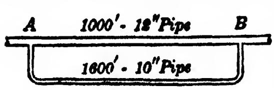

FIG. 17. Looped pipe.

Looped pipe (Fig. 17). Discharge from each branch is found from the fact that the pressure drop from A to B is the same in each.

Example. Find the pressure difference from A to B to give a flow of 5 cu. ft. per sec. and find the flow through each pipe.

For the same friction head, the discharge q varies as $(d^5/l)^{1/2}$, approximately. Hence the ratio of discharges is $(12^5/1{,}000)^{1/2} : (10^5/1{,}600) = 15.7 : 7.75$ or nearly $2 : 1$, which gives values of 3.33 and 1.67 cu. ft. per sec. for the two branches. The corresponding lost heads are 6 and 5.8 ft. (Fig. 14). A head of 5.9 ft. will give discharges of 3.2 and 1.8 cu. ft. per sec., as required.

Pump pipe lines. The general problem is selection of pipe for the greatest economy. The pumping head is the sum of the static head and the friction head, the latter varying as d^5 for constant discharge.

Example. Let the pump supply a reservoir with 600 gal. per min. against a static head of 60 ft. through a pipe 2,400 ft. long. Valves and bends increase the equivalent length to 2,500 ft. Select the pipe.

$q = 1.335$ cu. ft. per sec. Head lost per 1,000 ft. is approximately 1, 2.5, 7.2, and 30 ft. for diameters of 12, 10, 8 and 6 in. respectively (Fig. 14). Pipes 6-in. or less diameter give too large friction loss. The total losses for 8-, 10- and 12-in. pipes are 17.5, 6.25, and 2.5 ft., to which the static head must be added to find the pump pressure. The most economical pipe will be the one for which the interest on first cost of pipe line plus the value of power lost in friction will be a minimum. A small change in diameter makes a large difference in friction head.

Pumping. Three cases are represented in Fig. 18. (*a*) The total head is the static head plus friction head and the net power required is $WH/550$ hp., where W = lb. pumped per sec. and H is total head. (*b*) The pumping head is the difference between the friction and static heads. The negative head at C should not be greater than 25 ft. Since the slope of the hydraulic gradient varies inversely as d^5 it is possible to control the pressure at C by a

proper selection of pipe diameter. (*c*) The pipe is arranged to eliminate negative head at *C*. The static head is the difference in elevation between *A* and *C* and the friction head is the pressure drop from *A* to *C*. Pipe *CB* is a conduit designed to carry the given discharge under head *h*. Its diameter is less than that of the line *AC*.

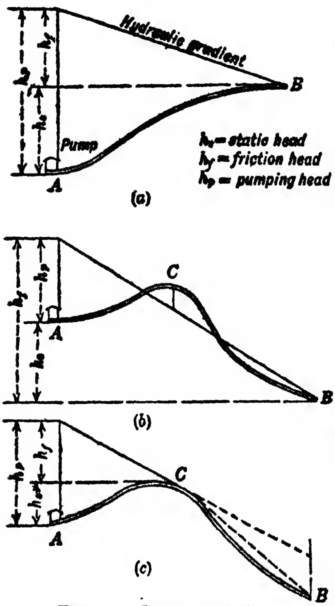

FIG. 18. Pump pipe lines.

Example. $AC = 2{,}000$ ft., $CB = 4{,}000$ ft.; elevation of $A = 20$ ft., $C = 50$ ft., $B = 0$. Find the power required to pump 4 cu. ft. per sec. through 12-in. pipe. (*b*) Fig. 14 gives $h = 7.9$ ft. per 1,000 ft. $= 47.4$ ft. Static head $= -20$ ft.; hence the pumping head $= 27.4$ ft. and hp. $= 12.45$ net. (*c*) If no negative pressure at *C* is permissible, the pumping head becomes $30 + (2 \times 7.9) = 45.8$ ft. and *CB* is designed to discharge 4 cu. ft. per sec. under a head of 50 ft. The diameter lies between 10 and 12 in.; hence the 12-in. pipe will run partly full. This can be avoided by partly closing a gate valve at *B*. Were the section *AC* made of 16-in. pipe, the friction head per 1,000 ft. becomes 1.9 ft., making the pumping head 33.8 ft., a saving of 26.6%.

Power delivered by a pipe is proportional to the product of the discharge and head at the delivery end. In Fig. 19, h_1 is a maximum when $q = 0$ and $h_1 = 0$ when $q =$ maximum. Power varies as $q(h_1 + v^2/2g)$ and has a maximum value when one-third of the static head is consumed in friction. Usually the value of the power is such that the pipe line is designed to consume but 5 to 10% of the total head in friction. Selection of a proper pipe diameter is governed by the same factors that control in pump pipe lines. Fig. 20 shows relations between head, power, and discharge for pipe delivering power.

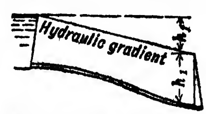

FIG. 19. Pipe with nozzle delivering power.

Example. Water under a total head of 1,000 ft. is brought to a 1,000-kw. Pelton wheel by a pipe 5,000 ft. long. The efficiency of the wheel is 85%. Design a pipe so that the friction loss shall be about 10% of the total head.

Assuming the head on the wheel $= 900$ ft., $q = 1{,}000 \times 550/(900 \times 62.5 \times 0.746 \times 0.85) = 15.5$ cu. ft. per sec. For cast-iron pipe in good condition, a 120-ft. head is required to discharge this quantity through 16-in. pipe and 40-ft. for 20-in. pipe (Fig. 14). 16-in. pipe will supply 16 cu. ft. per sec. with a loss of 125 ft. or 12.5%, which is the amount required to give 1,000 kw. under 875-ft. head, while 20-in. pipe will give the same power with a loss of 3.5%, the discharge being 14.5 cu. ft. per sec. After 10 to 15 yr. service the 20-in. pipe will maintain the required power with a loss of 6% and discharge of 15 cu. ft. per sec. (Fig. 15 with $C = 100$.)

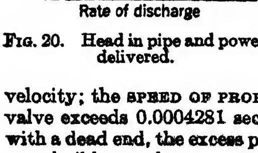

FIG. 20. Head in pipe and power delivered.

Water hammer or ram is the shock or blow produced by the dynamic action of water when the flow is suddenly checked by rapid closing of a valve or by other obstruction. The sudden decrease in velocity sets up a pressure wave which produces a maximum excess pressure of $p = 63v$ lb. per sq. in. where $v =$ change in velocity or "extinguished" velocity; the SPEED OF PROPAGATION is about 4,500 ft. per sec. If the time of closing the valve exceeds 0.0004281 sec., $p = 0.0271v/t$. If the pressure wave enters a branch pipe with a dead end, the excess pressure may be increased two- or three-fold; a series of branches may build up a dangerous pressure.

When the velocity in a long pipe supplying power to a water wheel is suddenly checked a pressure wave is built up which travels back to the reservoir and, owing to the elasticity of water and pipe, forces water back, thus producing a wave of reduced pressure. The result is establishment of an oscillating wave with gradually decreasing amplitude and period depending on the length of pipe. Water hammer may be greatly reduced by the use of air chambers on pumps and of surge tanks on pipe lines supplying water wheels; automatic relief valves employing springs are not as good. Velocity should never be checked suddenly; hence the valves are designed to close slowly. Allowance should be made for water hammer in design of pipe.

Design of pipe. Determination of diameter usually involves selection of a standard size that will furnish the required discharge under given conditions. Diagrams for selection of diameter give as great accuracy as conditions warrant. The roughness factor is so uncertain that discrepancies of 10% or more between calculated and actual discharge may be expected.

Cast-iron pipe, owing to its great weight in proportion to strength is too costly for mill supply lines. The relatively short life of these lines does not justify paying for the extraordinary longevity of cast iron in such service.

Wrought-iron and steel lap- and butt-welded pipe are used for distribution of water, gas, and steam in sizes 1/8 in. to 15 in. nominal diameter and in three weights, standard full-weight, extra-strong, and double extra-strong. Special pipe for hydraulic machinery capable of withstanding internal pressure of 10,000 lb. per sq. in. is made by boring solid steel forgings. Most lap- and butt-welded pipe now on the market is mild steel but is often sold as wrought-iron. Large lap-welded steel pipe can be furnished in any diameter in thickness from 1/8 to 1 1/4 in. Forged flanges and connections are furnished in all sizes. Standard sizes are given in Table 20.

Welded steel pipe 13 in. diameter and over, and smaller, if light-weight, can be made in local shops or at the shops of larger mining companies, if bending rolls and welding equipment are available. Edges should be beveled; such joints are as strong as the sheet itself. In laying, it is common practice to weld 30-ft. lengths together on the ground, providing slip joints every 200–500 ft. Coefficient of expansion is 0.0000084 in. per ft. per deg. F.

Flow through wrought-iron and steel pipe should be calculated for the actual internal diameter, which differs considerably from the nominal diameter. Small pipe is generally employed in short lengths with many elbows, valves, and other fittings; hence secondary losses of head play an important part. Table 21 gives dimensions of small sizes of standard full-weight pipe and the flow that may be expected for given pressures and equivalent lengths. (Williams and Hazen, *Hydraulic Tables*, Wiley.)

Riveted-steel pipe has been rendered substantially obsolete by modern advances in welding.

Wood-stave pipe, consisting of staves of cypress, white pine, fir, or redwood, banded together with steel bands, is much used where lumber is cheap and steel and concrete relatively expensive. It is suitable for diameters of 16 in. to 20 ft. and, with normal banding, for pressure heads up to 100 ft. With special banding, 3-ft. pipe is good for heads up to 400 ft., 4-ft. to 350 ft., 5-ft. to 290 ft., and 6-ft. to 240 ft. The pressure should be sufficient to keep the wood saturated. CONTINUOUS WOOD-STAVE PIPE is built in place, the lower half being assembled in a cradle and the upper half assembled over a pipe ring. Staves break joints, and end connections are made watertight by the use of a steel tongue which fits into saw kerfs in each stave. Bands are not tightened until the wood is thoroughly saturated. STAVES are from 1 1/4 to 2 1/2 in. thick and 6 to 8 in. wide. They are cut with true cylindrical surfaces and radial edges. They are bundled for shipment in 10-, 20-, and 24-ft. lengths. BANDS are 3/8 to 3/4 in. diameter and are designed and spaced to carry total hoop tension due to pressure in addition to swelling pressure of the wood. This latter may be assumed at 100 lb. per sq. in. Table 22 gives data on continuous-stave pipe.

Table 22. Continuous wood-stave pipe; untreated fir

Inside diam., ft.	Staves, thickness, in.	Bands, diam., in. *a*	Lumber for staves and saddles, bd. ft. per 100 lin. ft. of pipe	Weight per ft., lb.		Price, $ per ft., f.o.b. Vancouver, B. C. (1938)	Erection cost per ft., cents (estimated)

a Band for 100-ft. head.

MACHINE-BANDED PIPE is cut and banded in the shop and pipe lengths are joined with standard cast-iron or special fittings. Staves are made with tongues and grooves, and banding is a continuous wire wound on under high tension. Flat bands are also used. It is available in inside diameters of 3 to 18 in., lengths of 6 to 20 ft., for heads up to 400 ft.

ADVANTAGES of wood-stave pipe are ease of transport, easy curves to radii of 60 pipe diameters made without special fittings, high carrying capacity, relative cheapness, and good durability (15 to 20 yr. for untreated fir). Kutter, n = 0.009 to 0.011; Hazen-Williams, C = 120.

NEVADA CONS. mill, at McGill, Nev., receives most of its water by gravity from a reservoir on Duck Creek, 9.5 mi. away and 105 ft. higher than the receiving tank at the mill, through a 32-in. pipe of which 40,000 ft. was laid with Douglas fir staves and 1/2-in. round bands; sills were spaced at 3 ft. (*109 J 857*). The total first cost (1907), including 10,000 ft. of 32-in. riveted-steel pipe in the line, was $180,000, or $4 per ft. Flow capacity, 20 to 21 cu. ft. per sec. In 1920, the ends of the staves were found to be rotted; repairs were made by enclosing the affected portions of the pipe in concrete jackets, about 6 in. thick and reinforced with small rods; the total length thus repaired was 1,500 ft. This line was still in use early in 1924 and was expected to last 2 yr. longer (*C. B. Lakenan, PC*).

Reinforced-concrete pipe comes pre-formed in diameters of 2 to 10 ft. and lengths of 3 to 5 ft. Large diameters are generally poured in place. The pipe is usually reinforced longitudinally with steel bars and transversely with spiral wire, wire mesh, or steel bands, to resist the total hoop tension. When the pipe is not poured in place, longitudinal reinforcement is designed to provide interlocking of adjacent sections so that when the cement joint is made a continuous pipe results. Reinforced-concrete pipe is usually employed for conduits and for pipe under low heads, although reinforcement can be designed for any desired pressure. THICKNESS OF CONCRETE averages 1 in., per ft. of diameter, being slightly greater for small sizes.

Open channels include flumes, conduits, canals, rivers, and closed pipes when the latter flow partly full. FRICTION HEAD appears as a drop in water surface, not as a loss of pressure; the drop in a given length is just equal to the head required to produce flow through that length. The condition is analogous to that of a pipe line laid on its hydraulic gradient. Flow in existing channels is measured directly when possible; in designing channels and in determining flow where direct measurement is impracticable the Chezy formula v =

$C\sqrt{RS}$ is used. Values of C for a wide range of conditions are given in KUTTER'S FORMULA,

$$C = \frac{41.6 + \left(\frac{0.0028}{S}\right) + \left(\frac{1.81}{n}\right)}{1 + \left(41.6 + \frac{0.0028}{S}\right)\left(\frac{n}{\sqrt{R}}\right)}$$

and BAZIN'S FORMULA,

$$C = \frac{158}{1 + N/\sqrt{R}}$$

Values of C depend in both cases on the roughness of the channel and on the hydraulic radius R; Kutter also introduces the slope S. His formula is most used in this country.

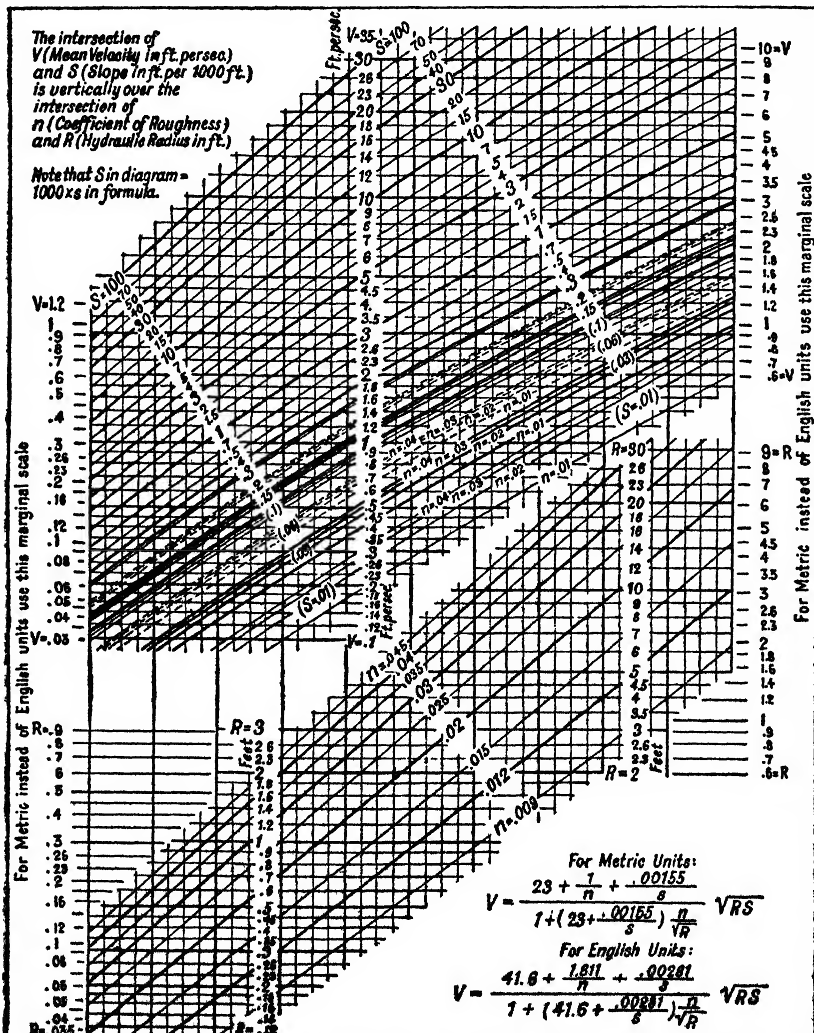

FIG. 21. Diagram for Kutter formula (*after Kennison*).

Value of coefficient of roughness in Kutter and Bazin formulas

	Kutter, n	Bazin, N
Channels of uniform section		
Well-planed timber, evenly laid	0.009	
Neat cement; best pipe	0.010	0.11
Cement, one-third sand; smooth pipe	0.011	
Unplaned timber; ordinary pipe	0.012	
Ashlar; brick work; new sewer pipe	0.013	0.29
Ordinary brick work and sewers; foul pipe	0.015	
Rubble masonry; rough concrete	0.017	0.83
Channels of non-uniform section		
Canals in firm gravel, section nearly uniform	0.02	1.54
Earth canals and rivers free from large stones and weeds	0.025	2.35
Canals and rivers in bad order	0.03–0.04	3.2

Limitations of Kutter's formula. Since the formula was designed to cover a wide range of conditions, considerable error is to be expected. For hydraulic radii greater than 10 ft., for velocities greater than 10 ft. per sec., and for slopes less than 0.0001, the formula should be used with caution. If the slope exceeds 0.001, the value of C for $S = 0.001$ may be used with an error less than the probable error from the formula. Great refinement is unnecessary since an error of 0.001 in the selection of the roughness coefficient n may change C 5 to 17%. The value of the formula depends largely on the proper selection of coefficient n; for smooth flumes and conduits, cleaned periodically, an error of 5% is to be expected; for canals and rivers in bad order, the formula is but a rough approximation.

Open-channel flow diagrams greatly facilitate the use of Kutter's complicated formula. Tables are also prepared giving values of C for all values of R, S, and n found in ordinary practice. One of the best diagrams, prepared by Kennison, is given by Fig. 21.

To find velocity when the hydraulic radius, slope, and roughness coefficient are known, enter the lower part of the diagram on the horizontal line representing the value of R, follow this line to the intersection with the given value of n, thence vertically to intersection with the assigned slope line; a horizontal line through this latter intersection determines the velocity.

Example 1. Given $R = 3$ ft., $n = 0.015$, $S = 0.0005$, find velocity. Enter at $R = 3$, proceed to intersection with $n = 0.015$. Project vertically from this point to line $S = 0.0005$ (marked 0.5). This point is on the horizontal line $v = 4.7$, which is the result required.

Example 2. An unplaned timber flume 2 ft. wide and 1 ft. deep is required to supply 10 cu. ft. per sec. What slope is necessary? $v = q/a = 5$ ft. per sec. $R = 2/4 = 0.5$ ft.; n for unplaned timber $= 0.012$. Vertical from intersection of $R = 0.5$ and $n = 0.012$ intersects line $v = 5$ on line $S = 0.006$ (marked 6) which is the necessary slope. For small values of S, as 0.00001, the position of the line representing S varies with the value of n.

Design of open channels. The Chezy formula shows that velocity increases as R increases. The constant C also increases with R, so that v varies nearly as $R^{2/3}$. Hence for a given discharge, that cross-section should be used which makes R maximum. This condition also makes the perimeter and area of the channel a minimum. A SEMICIRCLE meets these requirements; hence a semicircular channel will discharge more water than any other form for given values of area, slope, and degree of roughness.

Fig. 22 shows the channels having the most advantageous elements. The depth of a RECTANGULAR FLUME should be one-half the breadth. This gives the least value of perimeter p, hence the least cost

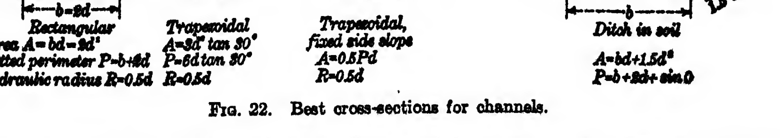

FIG. 22. Best cross-sections for channels.

for the flume and also the least area for given discharge, hence the least cost for excavation. The best TRAPEZOIDAL SECTION is one-half hexagon. If the side slopes are fixed by the nature of the soil, they should be tangent to a circle of radius d as in Fig. 22. The foregoing sections are not used for UNLINED DITCHES because a shallow ditch is cheaper to dig and maintain. AVERAGE DEPTH is $d = 0.5\sqrt{A}$, where d = depth in ft. and A = area in sq. ft. SIDE SLOPES depend on the material; usual values are 1 : 1, 1.5 : 1, and 2 : 1. For average loam use 1.5 : 1 (Fig. 22).

Velocity of water should be great enough to prevent deposits of silt and growth of weeds but should not be sufficient to erode the bottom of the channel; 2 ft. per sec. will prevent deposits. The following values of mean velocity are safe against erosion (*Peele*):

Very light loose sand	1.0 –1.5	Conglomerate, cemented gravel, soft rock	6.0– 8.0
Average sandy soil	2.0 –2.5	Hard rock	10.0–15.0
Average loam or alluvial soil	2.75–3.0	Concrete, water carrying coarse sand	7.0–12.0
Stiff clay or ordinary gravel	4.0 –5.0	Concrete, water carrying fine sand	15.0–20.0
Coarse gravel, cobbles	5.0 –6.0		

The usual velocity for ditches is 2 to 3 ft. per sec., which requires a slope of 3 to 7 ft. per mi. If the available slope is greater than this, the ditch must be lined or else a series of vertical drops introduced. These drops may be wooden or concrete weirs or ramps. The ROUGHNESS COEFFICIENT for unlined earth ditches is usually taken $n = 0.0025$.

Seepage losses in earth ditches may be as high as 25%; they may be reduced or almost eliminated by linings, which also permit greater velocity and prevent weed growth. LININGS may be puddled clay, road asphalt, or 2 to 4 in. of concrete, placed in position without forms on slopes 1 : 1 or less. Concrete practically eliminates seepage.

Freezing may occur in conduits if the flow of water is reduced below some minimum velocity, dependent upon the temperature. Radiation, particularly in a pipe, is not enough to cause freezing of running water, except in very small pipes or where velocity is very low.

Uniform cross-section is desirable; any change in section causes loss of head by impact and reduces flow. A smooth channel with small changes in section should be regarded as a rough channel in selecting a coefficient of roughness.

Example 1. Design an unplaned timber flume to deliver 20 cu. ft. per sec. with a slope of 0.001.

For the most economical section, $b = 2d$, $A = 2d^2$, $R = 0.5d$, $n = 0.012$. Use Fig. 21 with trial values of d; for values of $d = 1.5$, 1.6, and 1.7 the velocities are 3.3, 3.5, 3.6, giving discharges of 15, 17.8, and 20.8 cu. ft. per sec. Therefore a flume 17 × 34 in. will give the desired flow.

Example 2. Design a ditch in average soil with end slopes 1.5 : 1 to discharge 100 cu. ft. per sec.

Assuming safe velocity = 2.5 ft. per sec., the area must be 40 sq. ft. $d = 0.5\sqrt{A}$, = 3.2 ft.; $A = bd + 1.5d^2$; hence $b = 7.7$ ft. Wetted perimeter $P = b(2d/\sin\theta) = 19.16$ ft. $R = A/p = 2.09$ ft. Required slope (Fig. 21) is $S = 0.0007$ or 3.7 ft. per mi.

Surge tank should be provided where a ditch or flume feeds a pipe line. Overflow from this tank, as well as from any spillway along the pipe line, should be led away so as not to undermine pipe-line supports or erode roads.

3. SITUATION OF MILL WITH RESPECT TO TAILING DISPOSAL

General considerations. Waste from a milling operation must be disposed of, if the plant is not to bog down in its own refuse. The bulk to be cared for may almost equal that of the new feed. Legal penalties usually prohibit simple discharge at the mercy of gravity, even where a convenient lake, hillside, or flat is available. As a result, the disposal problem is not infrequently a deciding factor in mill location, particularly when the plant is a large one, serving a mine with assured long life, such as UTAH COPPER, or MIAMI. The tailing discharged by UTAH COPPER in one year, at 50,000 tons daily plant capacity, would cover 200 acres to a depth of 50 ft. (assuming 80 lb. solid per cu. ft. of deposited tailing).

The first question to be decided in a tailing-disposal problem is whether the tailing has probable future value by reason of mineral content, or possible use as a more or less comminuted nonmetallic, *e.g.*, road ballast, concrete aggregate, sand, or filler. If it has, it should be impounded in such a way as to make rehandling as easy and cheap as is consistent with costs of impounding; materials of different characters should be segregated, *e.g.*, coarse from fine, or high-grade from low-grade; and loss by wind and water should be guarded against.

If final immediate disposal is indicated, and unrestricted gravity disposal is not available, a variety of factors enter the problem, *viz.*: (*a*) Maximum economy requires gravity flow to destination; (*b*) gravity disposal uses water as a carrier and not all of this can be recovered; (*c*) mechanical elevation of tailing and the accompanying water may be a necessary preliminary to gravity disposal; mechanical stacking of dewatered sand tailing is an alternative; (*d*) areas of land may have to be acquired solely for tailing disposal; (*e*) special precautions may need to be taken against pollution of streams by soluble or suspended matter; (*f*) special haulage facilities may be needed; (*g*) in a few cases, the tailing has enough present market value to become a source of revenue, or at least to pay for disposal.

Direct loading into cars is a common method of disposing of coarse waste, especially that produced by hand sorting or by dry methods of concentration, as in LAKE SUPERIOR

"rock houses," WISCONSIN zinc mills, coal washers, magnetic iron concentrators, and sink-float plants. At wet-concentrating mills, the advantage of this method, even where gravity disposal is utilized for finer tailing, is that it avoids waste of the large volume of water that would be required to flush coarse material down a flume.

Former practice in SOUTHEASTERN MISSOURI was to dewater sand tailing in an elevated tank from which the settled product passed through spigots into cars drawn to a dump by locomotive. This plan is now obsolete, but in modified form (tailing mechanically dewatered before transfer to a bin) is still practiced in some places. At BUNKER HILL & SULLIVAN, sand tailing is occasionally diverted from an elevated gravity flume into railroad cars and hauled away for ballast. Tailing from the leaching vats at NEW CORNELIA is loaded by truss excavator into the same cars that bring the crushed, raw ore to the plant. Unusual circumstances at the MOCTEZUMA mill formerly required conveyance of deslimed sand tailing across a gulch by aerial tram; later the flotation tailing was flowed by gravity to settling ponds.

Gravity flushing of wet tailing of medium to fine size is always adopted if conditions permit; the method may require assistance of mechanical elevators, and is frequently employed in such a manner as to permit recovery of water. Design of a tailing launder requires special attention because: (*a*) it is usually longer than any launder inside a mill and, if given a grade steeper than is actually necessary, will sacrifice an undue amount of available head; (*b*) it carries a larger volume than individual mill launders and should be designed to do this without the addition of valuable water for flushing; (*c*) abrasion, while no more severe than in mill launders conveying the same material, demands more extensive renewals; linings should therefore be specifically designed for durability and ultimate economy.

Velocity of flow required for transportation of tailing in rectangular flumes depends on the size of the grains, their specific gravity, and, to a lesser extent, on the dilution of the pulp.

Mill tailing is usually siliceous (sp.gr., 2.6) and contains about 25% solids; on this basis safe velocities are given in Table 23.

Table 23. Velocities in tailing launders

Size of grain; all through:		Velocity required, ft. per sec.
Mesh	Mm.	
200	0.074	3.37
100	0.147	3.8
48	0.295	4.5
20	0.833	6.0
8	2.362	7.8
3	6.680	10.0
2	9.423	11.5

Table 24, calculated by Kutter's formula (Fig. 21), using $n = 0.015$, gives velocities for various sizes of straight launders, at slopes ranging from 5 to 50 per 1,000. For unplaned lumber lining in good condition ($n = 0.012$), the listed velocities should be increased by 25%. For rough lining ($n = 0.02$), multiply the tabular velocities by 0.7. Curves and turns and different specific gravities will require further modification of the tabular values. (See also Art. 6, and Sec. 18, Art. 16.)

Table 24. Launder velocities by Kutter's formula (n = 0.015)

Launder dimensions, width × depth, in.	"Mean radius" (R), ft.	Feet per second for slopes in in. per ft. indicated below					
		1/16	1/8	1/4	3/8	1/2	5/8
8 × 2	0.111	1.5	2.00	2.65	3.1	3.6	4.00
12 × 3	0.167	2.00	2.8	3.9	4.75	5.4	6.00
18 × 4 1/2	0.25	2.7	3.75	5.1	6.3	7.2	8.00
24 × 6	0.33	3.25	4.7	6.4	7.9	9.0	10.15
30 × 7 1/2	0.415	3.9	5.4	7.5	9.4	10.7	12.0
36 × 9	0.50	4.5	6.25	8.75	11.0	12.4	14.0
42 × 10 1/2	0.584	5.1	7.25	10.0	12.6	14.3	16.0
48 × 12	0.666	5.7	7.75	11.1	13.75	15.7	17.5
54 × 13 1/2	0.75	6.6	8.6	12.0	14.7	17.0	19.0
60 × 15	0.833	6.5	9.2	12.8	15.7	18.75	20.25
66 × 18	0.92	7.0	9.75	13.75	17.0	19.5	21.7
72 × 18	1.00	7.5	10.25	14.5	18.0	20.6	23.0

Lining. At BUNKER HILL & SULLIVAN the sides of a wooden tailing launder, 24 in. wide, are lined with concrete slabs, 1 ft. square and 1.5 in. thick, or white-iron plates of the same size, 1 in. thick, or with discarded elevator belt with the rubber-protected side against the walls. The bottom is riffled transversely, at 24-in. intervals, with 3/4-in. white-iron strips 6 in. wide, standing on edge; sand resting between the cleats prevents wear on the bottom (*S. A. Easton, PC; 120 P 526*). The slope is 3/8 in. per ft. At UNITED EASTERN, fine-crushed cyanide tailing (46% water) is distributed by gravity through 6-in. slip-jointed iron pipe laid with 3° (5/8 in. per ft.) minimum slope.

Impounding of tailing has three purposes: (*a*) to save the solid for future treatment; (*b*) to give opportunity for settling and recovering water; (*c*) to avoid pollution of streams. Tailing ponds may be formed by excavation in earth, by concrete dams, or, more commonly, by dams formed from the tailing itself. Impounding dams are frequently used to catch the water remaining in the thickened product of mechanical dewaterers.

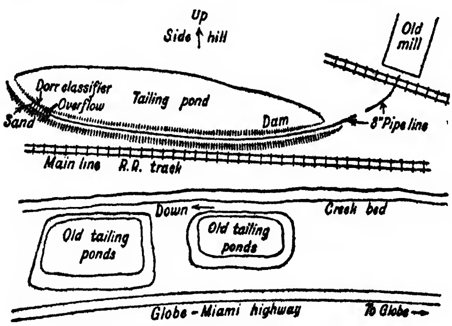

FIG. 23. Plan of tailing dam, Old Dominion.

Tailing dams. To build a stable dam with maximum slope of face requires that most of the slimes be removed before the sands are placed. The slime is then deposited separately behind the sands, and fills the pores therein in such a way as to maintain stability.

Most tailing dams are built from a launder or pipe supported on trestles close to the line of the face of the dam. The bottom of this launder or pipe is provided with metal-bushed holes at regular intervals (5–10 ft.) through which the roughly classified coarsest sands, which travel on the bottom, drop, while the fine sands and slimes flow on to the end and are led through a lateral launder or spout back from the face and toward the central pool. Further desliming takes place as the discharged sands pile up. Cleaner sand may be obtained by hanging small conical-pocket classifiers from the main launder. Occasionally rake, drag, or screw classifiers, traveling on a track on the dam, are used for desliming; or the separation may be made in the mill, sending sand to a stacker belt and delivering slimes only to the pond. In such event the retaining dam must be provided independently.

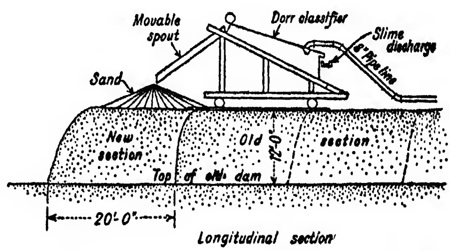

FIG. 24. Old Dominion method of building tailing dam.

At OLD DOMINION, 700 tons per day of <48-m. flotation tailing, 56% <200-m., in a pulp containing 20 to 25% solids, was flowed by gravity through 8-in. steel pipe 1,600 to 3,600 ft. at any convenient grade (50 ft. available fall) to a Dorr duplex classifier at the face of the tailing dam (Fig. 23). The classifier was mounted with its motor on a truck and was periodically moved ahead on a 20-ft. section of track, a corresponding length of pipe being provided. Sands, constituting about one-third of the solids, were deposited as shown in Fig. 24, forming a long narrow dam on a hillside; slimes discharged sideways into the pond. The dam section, shown under construction, was 12 ft. high and 12 ft. wide at the top, with side slopes of 45°. When a 12-ft. layer was completed to the limit of its width (200 ft.), another layer was started on top. Maximum height was 30 ft. above ground. One man attended the classifier and shaped the dam. The cost, 2 1/2¢ per ton, was relatively high because of the long narrow pond. Water was carried through the dam by a wooden standpipe.

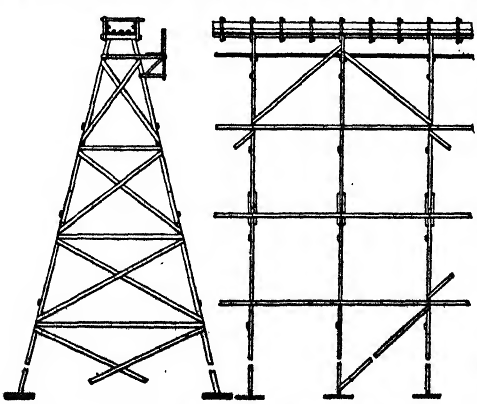

FIG. 25. Tailing launder and trestle, Inspiration.

At INSPIRATION, 14,200 tons per day of table and flotation tailing (94% <48-m. and 52% <200-m.), carrying 22.6% solids, was disposed of entirely by gravity. About 50% of the total circulating water, amounting to 4,600 g.p.m., was recovered just outside the mill by sending all table tailing plus part of the flotation tailing to a system comprising sloughing-off tanks with overflow to Dorr thickeners. The thickened products, plus the unthickened portion of flotation tailing, averaged 31.5% solids. This flowed by open launder 3,000 ft. to the nearest corner of the tailing dam, roughly square

in plan, thence by one of two elevated launders (Fig. 25), each about 5,000 ft. long, for distrib... around the perimeter. Launders were 4 ft. wide, 2 ft. deep, of 2-in. plank with battened joints, at uniform grade of 14 in. per 100 ft. Collars at 3-ft. intervals were of 4 × 6-in. sill and 2 × 4-in. posts and cap. The trestle (Fig. 25) ranged from 30 to 70 ft. high. Bents were spaced 12 ft. For bents up to 50 ft. the legs and caps were 4 × 6-in., battered 3 in 12, transversely braced in 12-ft. panels with 2 × 6-in. cross braces. For higher bents, the posts were increased 50 to 100% in section. A walkway 2 ft. wide with handrail was carried at one side of the flume Longitudinal bracing was effected by means of purlins spaced 12 ft. and slant bracing as shown in Fig. 25. The total load was 750 lb. per linear ft. Total lumber for a 30-ft. trestle was 900 bd. ft. per 12-ft. section.

Sand was deslimed in automatic cones (Fig. 26) 15 1/2-in inside diameter at the top, 2-in. diameter at the bottom, and about 3 ft. 2 in. deep, made of No 20 galvanized sheet. The cone was suspended by straps from counterweighted levers *a*. The valve rod *b* was fixed in position so that when the cone was filled with pulp at low density the valve closed. As sand collected and the weight of the cone increased, it dropped somewhat and the valve opened, discharging thickened sand

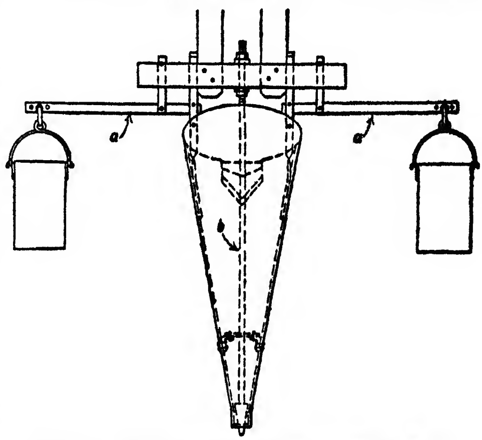

FIG. 26. Desliming cones, Inspiration tailing dam.

The cones were spaced at 12-ft. centers along the trestle. They were fed through 3/4-in. pipes inserted through the side of the flume. Sand and slime were discharged through short spouts, the former to a marginal pile and the latter to the enclosed pond. (See Fig. 27.) Of 400 cones installed, 250 were in use at a time; one man per shift watched 80 cones and 1,000 ft. of flume. Other labor included a boss and three men per shift. Wet sand settled to a slope of 1 1/2 to 1. The marginal pile was raised to a height of 40 ft., with a top width of 12 ft. When the enclosed area was filled with slime, a new trestle was erected on top and about 80 ft. back from the edge of the preceping pile; the resulting terraces were necessary to prevent leakage. In Feb. 1923 the fourth marginal pile had reached 126 ft. above the lowest point of ground; lower ponds were then started, as no higher level could be reached without pumping. Table 25 gives costs. Prior to 1920, about the same annual tonnage was distributed to four smaller ponds at costs ranging from 2.65¢ to 3.71¢ per ton. Water recovery was about 50%. Triplex pumps delivered the overflow of the thickeners against a head of 125 ft. with power consumption of 0.80 kw.-hr. per 1,000 gal. at a total cost of 1.25¢ per 1,000 gal. Water from the pond was returned by centrifugal pumps against a head of 280 ft., with consumption of 3.23 kw.-hr. per 1,000 gal. at a total cost of 5¢ per 1,000 gal.

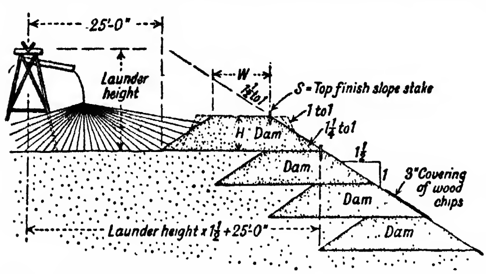
FIG. 27. Section of tailing dam, Inspiration.

At MIAMI, the procedure when discharging 7,000 tons of flotation tailing daily, 98% <48- and 55% <200-m., in a pulp containing 27% solids (approximately 3,300 g.p.m.), was as follows: The material flowed by gravity through 4,000 ft. of 18-in. redwood stave pipe under a head of 26 ft. to a penstock. Velocity in the pipe was low enough to allow sand to settle along the bottom and protect it from wear. The pipe was laid on the ground, at no special grade (at one point passing over a low hill). It was carried across the slime pond on a trestle. When necessary to raise this trestle, sand was allowed to flow through holes in the bottom of the pipe, forming a ridge across the middle of the pond. From the penstock two launders extended, one for 2,400 ft. and one for 1,600 ft., along the face of the dam in opposite directions. The launders were V-shaped, with 24-in. sides, made of 2-in. plank, set on a grade of 1/8 to 3/16 in. per ft. and had V-notches to the full depth on the dam side at 20-ft. intervals.

Table 25. Cost of tailing disposal at Inspiration mill (cents per dry ton)

Year	Tons solid	Launders and trestles	Drain	Operating labor	Miscel.	Total
1920	4,943,000	0.488	0.168	0.490	0.224	1.370
1921	884,950	1.420	0.463	0.539	0.168	2.690
1922	3,534,000	1.120	0.090	0.550	0.460	2.220
1923	4,957,730	1.620	0.100	0.570	0.120	2.410

They were supported on a trestle (Fig. 28) 30 to 60 ft. high, 25 ft. back from the outer edge of the dam. The bents, 10 ft. apart, were made of 4 × 4-in. posts and 2 × 4-in. braces. The entire flow in each launder was discharged through its lowest notch, and directed toward the face of the dam by an apron 9 ft. long, 4 ft. wide, and 1 ft. deep, made of 1-in. boards. The sands settled on the bank, while slime flowed inward toward the pond. When the sands had accumulated to a depth of 6 ft., the next higher notch was opened, and the process was repeated until a 6-ft. layer had been deposited back to the penstock. This part of the operation required one man per shift, with another man and a foreman on day shift, or five men per day. A dam 6 ft. high was next formed along the outer edge of the pile by an American railway ditcher operated by three men. It required 45 days (one shift) to complete a dam along the whole length of the tailing pile. The outer face of this dam, sloping 1 1/2 to 1, was continuous with the general outer slope of the whole pile; no terracing was necessary. One 6-ft. dam provided retaining space for 6 months, or 1,250,000 tons. The highest point of the dam (early 1924) was 200 ft. above ground. Wood chips, collected on screens attached to Dorr classifiers in the mill and amounting to 3 or 4 tons (dry) per day, were spread loosely in a 3-in. layer over the outer slope of the pile to alleviate nuisance from blowing dust. The cost of gravity disposal (1923), including trestle and launder building, ditcher operation, labor, and maintenance, was 1.61¢ per ton; the additional cost of collecting, transporting, and spreading wood chips was 0.75¢ per ton of tailing.



W = finished width of top when dry. H = height of dam for stacking dry sand. For stacking wet sand for finished top width W, place stake at S; for semi-wet sand move slope stakes in $H/4$ from S.

FIG. 28. Section of tailing dam, Miami Copper Co.

In 1937, 17,000 tons per day was first thickened to 52% solids in a 325-ft. thickener just below the mill, then pumped against 80-ft. head through 18-in. wood-stave pipe 16,000 ft. to a dam. Here the pulp was diluted with dam water to 40% solids, and sands discharged through gate valves spaced 40 ft., one at a time. The deposited sands were then built up into a border crest, 6 to 9 ft. high, with a power shovel.

UTAH COPPER Co. (1938) discards 50,000 tons per day, of which 85% is <200-m. The disposal area is a tract of 6,300 acres, comprising a gently sloping foothill and a swampy flat. Available fall below the mill outlet is 120 ft. A dike 35 ft. high, 25 ft. wide at the top, 8.3 mi. long, at approximately 13,300 ft. from the mills, prevents encroachment on the main line of the Union Pacific R. R. This dike was built with mine waste. Pulp carrying 20 to 25% solids is discharged at one point well up on the hill and fans out, depositing solids, while clear water collects behind the dike, whence it is drawn through sluice gates into a parallel gathering ditch. An area of 6,100 acres is now covered to an average depth of 25 ft. by the 260,000,000 tons deposited since 1907. Some of the early gravity tailing contains sufficient value to justify reworking, although tardy recognition of this possibility resulted in none too favorable disposal.

OMEGA GOLD MINES, Larder Lake, Ont., discards 525 tons per day, of which 68% is <200-m. Pulp with 33% solids is pumped by 5-in. rubber-lined pumps through 6-in. wood-stave pipe on 5-ft. trestles around the periphery of a dam about 810 ft. square; this was started 5 ft. high on a flat with earth scraped up by a small caterpillar dragline. Spigots lined with cast iron, spaced 10 ft. apart, discharge sands through transverse sublaunders; this sand is shoveled up into a border crest 10 to 12 in. high. Slime is drawn off by 90° reducing elbows at 100-ft. intervals and discharged into the pond. The dragline raises the wall about 5 ft. in the autumn for winter storage. Water is withdrawn through an uptake weir at the center of the pond, thence through two 8-in. pipes in parallel through the dam to a return-water sump. Freezing at −48° F. caused no interruption. Cost for 12-mo. period 1937–8 was 3.5¢ per ton.

COPPER QUEEN discharged 5,000 tons per day of flotation tailing thickened to 50% solids in one 200-ft. and two 75-ft. thickeners. Spigot product was flowed in a 23 × 10-in. launder (slope 1.6 in. per ft.) to a trestle with bents 25 ft. high on 14-ft. centers. Sand spigots discharged during 4 to 8 weeks through one set of sublaunders directed toward the crest; thereafter the deposited sand dried while current sand was discharged at another point. Dried sand was shoveled into a border crest 3 to 4 ft. wide by 3 ft. high. Water passed through an uptake weir at center of pond, thence through a cribbed tunnel to a return-pump sump for 220-ft. lift back to storage. Lime and iron salts in the tailing water prevented dusting.

NACOZARI. Flotation tailing, 2,300 tons per day, contained 58% <200-m.; pulp at 19% solids flowed 4,000 ft. in a 22 × 10-in. launder, sloped 3/16 in. per ft., to dam trestle with bents on 14-ft. centers. Sands were removed by spigots or thickening cones. Water (including flood water) flowed over an uptake weir at center and thence by concrete tunnel through the dam. Dams were 140 ft. and 100 ft. high.

MORENCI (1936) discarded 5,000 tons per day of flotation tailing thickened to 42% solids in one 200-ft., one 130-ft., one 100-ft., three 60-ft., and two 50-ft. thickeners at the mill; thence by ditch and flume 15,000 ft. to the dam. Here 8-in. pipe in 20-ft. lengths, sloped 0.9 in. per ft., and discharging through holes at 6-ft. centers, was supported behind a wood fence 2 ft. high, against which the sand deposited. The steps of the dam were 2 ft. high. Over-all water recovery was 70%.

CARDINAL. Tailing, 300 tons per day, 60% <200-m., in pulp with 45% solids, is lifted 16 ft. by pump, and flows thence by gravity through 2,000 ft. of 3-in. pipe to the dam. Sands are deposited by 2-in. spreader roses, 20 ft. long, with hose, spaced 50 ft. Cement (1 sack per 40 tons) is added during 2 to 3 hr. per shift as a setting agent.

CHINO discharges 13,500 tons of flotation tailing per day. Pulp, at 22% solids, flows through 30-in. wood-stave pipe (slope, 0.07 in. per ft.) 6,600 ft. to a 20 in. wood-stave distributing pipe around the pond. Holes at 10-ft. intervals discharge sand to sublaunders for deposit. Crest border is maintained by a traction ditcher. Steps are 16 ft. high. Water recovery is 60%.

YELLOW ASTER. Tailing, 20% <200-m., 30% solids, is pumped 1,400 ft. through 4-in. pipe to a 5-in. pipe header on a low trestle along a dam. Outlets at 30-ft. centers consist of 1 1/2-in. nipples with 16-ft. lengths of rubber which deposit sands close to the dam face; slimes discharge into the pond.

EL POTOSI delivers 2,400 tons per day through 3,200-ft. launder lined with cast iron to foot of the dam; thence by Wilfley pump through 6-in. pipe 700 ft. along dam crest; there sands discharge through 1 1/2 × 18-in. nipples spaced 4 ft. Water is skimmed by weirs. Dam steps are 10 ft. high. Coarseness of sand and oxidation of pyrrhotite make the dam coherent.

HARMONY MINES. A rake classifier on a truck along the crest de-sands tailing carrying 18% solids. Reclaimed water from the dam is filtered and cake conveyed 60 ft. to a dump.

SILVER DYKE. Tailing is de-sanded in an Akins classifier, sand going to the dam by belt; slime is thickened, the water re-used, and spigot product pumped to a pond.

CLIMAX. See Sec. 2, Fig. 142.

Clarification of tailing water to avoid stream pollution is required by law in certain states. A coagulant is ordinarily necessary to increase the settling rate or to get an overflow sufficiently clear. Common coagulants are: acid sodium sulphate (saltcake), aluminum sulphate, caustic starch, ferric sulphate, formic acid, hydrochloric acid, lime hydrate, sodium aluminate, sulphuric acid, zinc sulphate.

Elevation of tailing is adopted either to stack comparatively dry tailing in a pile or to extend the radius of gravity disposal. The most commonly employed means of elevation are: (*a*) inclined trams; (*b*) sand wheels; (*c*) belt-bucket elevators; (*d*) inclined belt conveyors; (*e*) centrifugal sand pumps; (*f*) air lifts.

Sand wheels up to 60-ft. diameter have been used in South Africa and are still retained at CALUMET & HECLA for transferring tailing from the main concentrator to retreatment works, on account of their simplicity, durability, and efficiency. For details see Sec. 18, Art. 20.

Belt-bucket elevators are used for tailing disposal in the Tri-State district but newer mills employ inclined conveyors handling dewatered tailing. When the disposal space within reach of the mill elevator and its distributing launder is exhausted, a second elevator of the same height is erected on top of the first pile, receiving its pulp through launder from the top of the first elevator, and distributing its discharge by a second launder. The system is extended in this manner until as many as three or four intermediate "dummy" elevators are installed in addition to the mill elevator and the final stacker.

Owing to the grade (2 in. per ft.) required for connecting launders, and an unavoidable drop of about 6 ft. at the upper end of each elevator, the combined lift of the elevators will be about twice the height of the final pile, and all water required for flushing through the successive launders (1.7 tons per ton of tailing) must be elevated the same distance. An average mill of the district discharges 25 tons and a large mill 45 tons of tailing per hr. At an average mill, elevator belts are 8-ply, 24 in. wide, with buckets 24 by 7 in., made of 10-gage steel, spaced on 18-in. centers; this permits three shifts of buckets during the life of one belt, which is usually about 18 mo. Average speed is 275 ft. per min.; average power for a system containing one or two dummies, 0.44 hp. per ton of pulp, equivalent to 1.18 hp. per ton of dry tailing deposited.

A new 60-ft. dummy elevator costs (1925) about $2,000 complete, itemized as follows: 136 ft. of belt @ $3.85 = $524; 90 buckets @ $1.31 = $118; 1 spout, $40; 15-hp. motor and material and erection of elevator structure, $1,318. COST of operation of a system containing five elevators will average, per year: power (300 days of 20 hr., 75 hp. @ 1.5¢ per hp.-hr.), $6,750; labor for maintenance and attendance, $250; total, $7,000, equivalent to 4.7¢ per ton for a mill of average size, or 2.6¢ per ton for a large mill.

Inclined belt conveyors represents standard practice in the lead belt of SOUTHEAST MISSOURI, where a single mill may dispose of 2,000 to 4,000 tons of sand tailing per day (*57 A 322*).

The sands are mechanically dewatered (shovel wheels are preferred) to 8 to 20% moisture and delivered to a rubber-covered belt conveyor, usually 24 in. wide, inclined 16°, and moving 300 to 350 ft. per min.; in one exceptional case the speed was 475 ft. per min. up 23° slope; in general, 18% moisture will cause tailing to slide on a 16° slope. The belt is usually lengthened by units of 75 ft., as the pile gains height. Idlers for this wet work must stand hard usage. The standard 5-pulley grease-lubricated type is in general use. Discharging from the belt may require assistance by air or water jets. Tailing is distributed from the end of the belt through semicircular launders (9-in. radius) of No. 10 sheet iron in 4-ft. sections. They are laid on the pile with a slope of 2.5 to 3 in. per ft. Flow is assisted if necessary by water pumped through a pipe from the mill to the upper end of the conveyor; in some cases

part of this flushing liquid is dropped on the flank of the sand pile, washing out a cavity to be concurrently filled with sand from the conveyor. Slime tailing was sometimes filtered through sand piles, yielding clear water to the reclaiming pond, but impounding dams for slime tailing are now practically always used.

Centrifugal sand pumps are now available in durable types and adequate sizes to stand the severe service of pumping large volumes of tailing. (For pumps in general mill service, see Art. 6, also Sec. 18, Art. 17.) Sands up to 1/8-in. size can be pumped safely, if carried by at least three parts of water; coarser sands are being pumped, but at the cost of excessive wear. Pulps below 48-m. can be pumped at a dilution of 1 : 1; and, in general, trouble due to sedimentation is less likely to occur with thick than with thin pulps. Pipes through which coarse pulps are being pumped should be inclined at least 20° from the horizontal, to permit complete drainage when the pump stops.

At UTAH CONSOLIDATED 950 tons per day of tailing (80% <200-m.) in pulp carrying 40% solids is pumped against a head of 35 ft., using a 6-in. Wilfley pump. BUNKER HILL & SULLIVAN lifted 600 tons of general tailing with 24,000 tons of water per day against a 25-ft. head with a 12-in. Byron Jackson pump direct-connected to a 75-hp. motor at 900 r.p.m. (*120 P 525*). MIAMI formerly used three 6-in. Wilfley pumps (with three others always in reserve) to lift 3,300 g.p.m. of tailing pulp carrying 22 to 27% solids (averaging 6,000 tons dry solid per day ground to 48 *mog*) against a total head of 46 ft. Each pump was driven at 1,020 r.p.m. by belt from a 50-hp. motor; the power requirement was 0.45 kw.-hr. per dry ton. The delivery pipe was 18 in. diameter and was steel for a short distance from the pumps, the remainder redwood; total length, 1,280 ft. The average pulp velocity was 4.2 ft. per sec. The expense per dry ton was: power, 0.594¢; labor and supplies for operation, 0.224¢; maintenance of pumping plant, 0.212¢; total, 1.032¢, not including labor on the dump. Wood pipe showed no wear after 18 mo. (*C. E. Chaffin, PC*). This system is now displaced, rearrangement of the milling process having made it possible to discard tailing by gravity from a higher level (see p. 20–37).

Air-lifts were installed at the CHINO COPPER Co. in 1919 to raise 12,000 tons of tailing per 24 hr. to a height of 40 ft., delivering into a gravity launder (*J. M. Sully, PC; 112 J 806*). Costs for the year 1923 were 1.028¢ per ton of dry solids lifted. The cost for a belt-bucket elevator previously used was 1.954¢ per dry ton. No trouble was experienced in starting the air lift, even under 32 ft. of settled slime. Experiments demonstrated the possibility of its use on tailing containing everything up to 1-in. size with 50% solids in suspension.

Possibility of utilizing tailing may have a bearing on the selection of the method for temporary disposal. Common uses for mill tailing are: (*a*) mine filling; (*b*) for retreatment; (*c*) for road building, railroad ballast, and structural purposes; (*d*) for recovery of soluble constituents from crusts formed by evaporation; (*e*) for agricultural purposes.

Mine filling. At the CHAMPION mine deficiency of coarse waste filling is made up by hauling mill tailing up to 1/4-in. size in railroad cars and dumping into a raise connecting with the working levels. The sand is distributed in the stopes by blowing through pipes up to 250 ft. long from a tank holding a charge of 1.5 tons, using air at 75 lb. pressure. The cost is 2¢ per ton of sand moved. Burning stopes in the LEONARD, TRAMWAY and WEST COLUSA mines, Butte, were filled with flotation tailing, both old and currently produced, of which 50% was <280-m. The material was sluiced through a 3,650-ft. flume, 23 in. wide, on 2% grade, in a pulp carrying 20 to 50% solids and 250 to 600 g.p.m. water. Pulp was conducted down the shaft in a 6-in. cast-iron pipe and distributed 800 to 1,000 ft. laterally through 4-in. pipe (cast and wrought) with bends of 4-ft. radius. A head of 100 ft. was usually satisfactory for distribution (*68 A 61*).

Retreatment of tailing by tabling, ammonia leaching, and flotation forms an important part of the present milling operations at CALUMET & HECLA (*117 J 277*), the material having been formerly deposited under water and along the shore of Torch Lake, from which it is reclaimed by suction dredges. (See Sec. 2, Fig. 11.) At ANACONDA, when starting the mill in 1901, slime tailing was saved for future treatment by collecting it in six earth ponds, each 300 by 600 ft. in area and averaging 15.5 ft. deep, the flow, when possible, being continuous through three ponds in series. Settled material was excavated by dragline scraper and piled alongside the ponds (*46 A 249*). In subsequent years, this accumulation afforded notable amounts of cheaply recovered copper. At CHINO a similar plan was followed during early operations, and later a 1,000-ton mill was erected to treat the accumulated tailing. At PANDA, 4,000 tons per day of a copper carbonate ore was concentrated by jigs and tables. The tailing averaged 5% Cu, easily recoverable by leaching, for which treatment it was impounded (*29 MM 137, 5 MMt 55*). At the SWEENEY mill, Kellogg, Id., 1,200,000 tons of jig, table, and flotation tailing, <20-mm. in size and averaging 1.9% Pb, was re-treated. The pile had been formed by the Joplin method of elevators and launders (see p. 20–39); it covered 20 acres, had maximum height of 70 ft., maximum slope of 20° 07′, a minimum natural slope of 4° 30′, and weighed 110 lb. per cu. ft. It was reclaimed by steam shovel, standard-gage cars, and locomotive, and inclined belt conveyor. (*119 P 869.*) At UTAH LEASING Co. old tailing (0.7% Cu as chalcopyrite) from the Cactus mill was reclaimed at the rate of 620 tons per day by steam shovel and 5-ton cars hauled 1,000 ft. by a steam locomotive.

In general, when disposing of tailing in expectation of subsequent re-treatment, the following precautions should be observed, where practicable, even at some additional cost (*58 A 178*): (*a*) when starting a mill, the earliest tailing should not be placed so that it will be buried under later accumulation, which will probably be of lower grade; (*b*) middling should not be mixed with tailing; (*c*) tailing

should be placed in a deep and narrow rather than a broad and shallow deposit, to facilitate reclamation; (*d*) sand and slime tailing should be separated; the latter is not only lower in grade but also needs no re-crushing before further treatment.

Road building and railroad ballasting consume important amounts of coarse mill tailing in the Tri-State, southeastern Missouri, Lake Superior, northern New Jersey and numerous other districts situated near populous communities. At the RICHARD mine, Dover, N. J., a large part of the hard, light-colored tailing from dry concentration of iron ore was sold for structural purposes within a radius of 100 miles (*115 J 973*). Two coarse grades, 2~3/4-in. and 3/4~3/8-in., sold for $1 per ton, and sand <1/8-in. for 80¢ per ton. The income from this source was a setoff against fine crushing for recovery of additional iron. The sink-float tailing from the AMERICAN ZINC, LEAD & SMELTING Co. mill at MASCOT, Tenn. (1 1/2 in. maximum size), is re-screened and classified into sized products suitable for various structural purposes; the largest consumption is for railroad ballast, but some was shipped as far south as Tampa, Fla. A finer material (80% <200-m.) was shipped as far as New Orleans, Memphis, and Washington, for use in street and road construction (*H. I. Young, PC*).

Brick of excellent quality and high acid resistance is made from ANACONDA flotation tailing, which averages 20% alumina; the same practice was applied to mill and cyanide tailing at the OPP mine, Oregon (*115 J 492*).

Agricultural uses. The fine limestone flotation tailing (85% <100-m.) at MASCOT finds a good local market as soil dressing because of its lime content.

4. TOPOGRAPHY OF MILLSITE

General. The slope of the ground selected for the millsite is not only a determining factor in the cost of construction, but also has an important bearing on the cost of operation. Steep slopes (25–35°) should be avoided, if possible; moderate slopes (5–15°) or even level sites are preferable. Terraced mills had some advantages for high-grade or coarse-grained ores treated by graded crushing and successive stages of gravity concentration. But a flotation mill with large-unit crushers and parallel grinding and concentration is better adapted to flat or gently sloping sites, so that the expensive many-terraced mill is seldom required and rarely built today. In the modern mill, crushing is almost invariably done in a building separated from and independent of the grinding and concentrating mill, and inclined conveyors distribute the crushed product to the mill-storage bins. Thence one drop is provided to the grinding mills, a second to the concentrating floor, and a possible third to the concentrate-handling plant. Such drops, with the necessary bench widths, can be obtained on a 10–15° slope. On a level site the storage bins can be raised on suitable foundations, inclined conveyors used for necessary elevation of dry ore, and pumps for wet material. The added operating cost is small and is largely offset by better and more ready supervision, and greater ease of repair. Building design is simplified, since standardized stock types of trusses can be selected, and the height of vertical members can be reduced to a few dimensions by bringing foundation walls or footings up to a common level at small expense. Such a building can be erected by men working mainly from the ground, with the assistance of a few gin poles. Cost data relating to the erection of typical mills are given in Art. 14.

The CONSTRUCTION FEATURES most affected by slope of site and type of mill are: excavation, retaining and foundation walls, design and erection of frame, with special reference to support of heavy or vibrating machinery and snow loads; natural lighting, and ease of enlarging. The OPERATING FACTORS most strongly influenced are: elevation and re-elevation of ore and its products, pumping and re-pumping of water, labor required for supervision, facility in making repairs, and replacements.

Excavations required for a terraced site are not only larger in volume than for a level or gently sloping site, but are also more expensive per cubic yard, owing to the difficulty of employing horse or mechanical traction in the constricted working spaces. For methods and cost of excavation, see Table 58. See also *Peele*.

Retaining walls are an essential feature only in a terraced mill, although occasionally required elsewhere. On a steep hillside in loose material, retaining walls must have exceptional solidity to withstand the combined settling effect of drainage and the jarring of heavy machinery. When benches are in rock, retaining walls become more or less ornamental only, and are sometimes omitted. Retaining walls generally serve also as foundations for building and equipment.

Foundations for the mill building (aside from retaining walls) need have only moderate bearing strength for mills of low average height; in such mills, both terraced and level, the massive equipment rests on the ground, leaving little but the walls, roof, cranes, and elevators to be supported by the vertical members of the structure. In tall mills, while it is possible likewise to place the heaviest crushers on the ground, provision must usually be made for carrying heavy and vibrating loads on fairly long vertical columns, and the foundations for these must be substantial. Safe bearing pressures for earth and rock are given in Table 26.

Design and erection. In a terraced mill considerable diversity will occur in the dimensions of the several panels and their individual members, calling for a large amount of detailed designing. Erection is retarded by the necessary distribution of structural elements over a large area and at numerous

levels. A tall mill also requires skillful and detailed designing; its erection is usually more rapid than that of a terraced mill because the materials can be assembled at a few convenient points and hoisted into place by one or two derricks. A low, flat building has the advantage of simplicity in design; standardized stock types of trusses can be selected, and the height of vertical members can be reduced to a few dimensions by bringing foundation walls or piers up to a common level at small expense. Such a building can be erected by men working mainly from the ground, with the assistance of a few gin poles. Cost data relating to the erection of typical mills are given in Art. 14.

Enlargement should be provided for in the original design; this is readily done, if the layout is on the UNIT PRINCIPLE, *i.e.*, with the machines so arranged as to constitute a plurality of independent mills in parallel; the size of each unit depending on the magnitude of the original undertaking. Thus a 500-ton mill might well consist of two 250-ton units; a 1,500-ton mill of three 500-ton units; a 5,000-ton mill of five units, etc. The larger the unit, the lower the first cost per 24-hr.-ton. Enlargements are made most easily at a terraced mill, since the direction of flow is usually directly down slope, with only subordinate amounts of lateral transfer of products, and additional similar sections at either end can be supplied with ore readily by an extension of the receiving bins, or by a distributing conveyor. A flat mill can usually be extended in the same manner, provided it has been designed originally in parallel units. A tall building offers the most difficulty, since its ore must be received at a central point and the flow is mainly vertical. BUNKER HILL & SULLIVAN doubled the original capacity of its No. 2 West mill by erecting a duplicate 5-story addition on the opposite side of its receiving bin.

Table 26. Safe bearing pressures, tons per square foot (*after Baker*)

	Minimum	Maximum
Rock equal to the best ashlar masonry..	25	30
Rock equal to the best brick masonry...	15	20
Rock equal to poor brick masonry......	5	10
Clay in thick beds, always dry.........	6	8
Clay in thick beds, moderately dry.....	4	6
Clay in soft beds	1	2
Gravel and coarse sand, well cemented..	8	10
Sand, dry, compact, well cemented.....	4	6
Sand, clean, dry......................	2	4
Quicksand, alluvial soils...............	0.5	1

Gravity flow of pulp and as nearly complete elimination of elevators and pumps as is possible are the main objects sought in mill design. In districts such as southwest Colorado, and the coasts of Alaska and British Columbia choice is practically limited to the terraced site, and in other localities, where ore or water or both can come by gravity to a mill having the necessary space for tailing disposal, also by gravity, the advantages of a terraced site probably outweigh its drawbacks. In other situations, requiring initial elevation of ore or water or mechanical elevation of tailing, the choice of a site and the decision as to type of mill demand careful investigation.

Type of mill. As between a tall or terraced and a one-level mill structure, the decision is based on comparison of the costs of the following items: (*a*) Initial elevation of ore; (*b*) initial elevation of water; (*c*) final elevation of tailing; (*d*) final elevation of concentrate; (*e*) intermediate elevation of ore and products; (*f*) re-elevation of water; (*g*) interest and amortization on excess cost of erecting and installing a terraced or tall mill; (*h*) increased labor charges, due to inconvenience of supervising operations on numerous floors; efficiency of extraction may be adversely affected for the same reason.

Initial elevation of ore to the top of the mill by means of the mine-shaft hoist can be performed at little or no expense above that required to deliver the ore at ground level; this is general practice in many districts. Other common methods of initial elevation are by chain-bucket elevator, inclined pan conveyor, inclined belt conveyor, and inclined trams or elevated trestles. For methods used at specific mills see Secs. 2 and 3.

At BUNKER HILL & SULLIVAN (*S. A. Easton, PC*) the entire feed for No. 2 West mill (50 tons per hr. of <1.25-in. material weighing 150 lb. per cu. ft.) is elevated by a belt conveyor 227 ft. long, inclined 22°, and rising 52 ft.; 5-ply belt is 20 in. wide, speed 187 ft. per min. Head pulley 42 in., tail pulley 30 in., 5-pulley troughing idlers. Operating power, including five feeders, one weigher, one pump, one distributer, and one sampler, is 18 hp. Operating cost, per ton: equipment (troughing and idler pulleys, etc.), 0.029¢; belting, total length, 465 ft., 0.068¢; power, 0.009¢; labor (cleaning, oiling, etc.), 0.217¢; total, 0.323¢ per ton.

At UTAH APEX (*J. H. Manwaring, PC*) a chain-bucket elevator 76 ft. long, inclined 71° and moving at 63 ft. per min., is used to lift the entire mill feed of 100 tons per hr. The drive is a 25-hp. motor which draws 11.2 kw. at full load, 7.9 kw. empty. Run-of-mine ore is fed from a track hopper by a steel-apron feeder driven from the tail pulley of the elevator. Keystone rivetless manganese 9-in. chain lasted 5 yr.; 9-in. Simplex rivetless manganese chain was still in use at the end of 5 yr. Buckets, 108 spaced 18 in., are 24 × 14 × 17 1/2-in., No. 8 steel; cost $10.61 each. The original cost of the elevator in 1913, f.o.b. plant, was $3,093. The total cost of repairs during 10 yr., including one entire replacement of chains and sprockets, was 0.715¢ per ton; power (@ 1¢ per kw.-hr.), 0.112¢ per ton.

Initial elevation of water. (See Art. 2.) In those cases where water must be pumped, elevating it to the storage reservoir may be more costly than elevation of ore. In general, pumps are more efficient, mechanically, than ore elevators, but the fact that they may be

required to lift as much as 20 tons of water for every ton of ore, and also to a higher level, makes it essential to keep down mill height, unless abundant water under natural head is available.

Final elevation of tailing is ordinarily unavoidable at any mill on level ground. If treating an ore from which it is possible to extract clean tailing at a fairly coarse stage, a tall or a terraced mill may have the advantage of being able to dispose of this portion of its tailing without further elevation; but at Bunker Hill & Sullivan, a tall mill on level ground at which some coarse-sand tailing is discharged, it is necessary to use a large tailing elevator with a lift of 25 ft. (*120 P 525*).

Elevation of concentrate. The importance of this feature is often exaggerated. Concentrate rarely exceeds 20% of the weight of original ore, and at most of the largest mills it ranges from 3 to 7%; hence, any design that provides an additional story or terrace solely to permit gravity disposal of concentrate will be unnecessarily expensive to construct, and is likely to be uneconomical in operation, if it throws additional work upon pumps or elevators at earlier stages of the process.

Intermediate elevation of ore in process can rarely be wholly avoided, even by the most steeply terraced mill.

Britannia, a flotation mill with seven terraces and a drop of 250 ft. in a horizontal length of 209 ft., requires only one elevator. Alaska-Gastineau, a table mill on a steeply terraced hillside, requires two sets of automatic skips (with 100-ft. lifts) and two bucket elevators. Silver Dyke mill (tables and flotation), with 11 terraces and a total drop of 150 ft. in a horizontal length of 277 ft., requires one elevator of 27-ft. lift and an inclined conveyor with 19-ft. rise, in addition to a number of sand pumps.

In general, the necessity for intermediate elevation is most pronounced in those mills treating an ore in which the valuable minerals occur as particles of graduated size, recoverable by a stage process of reduction and giving rise to important quantities of middling products which must be returned for re-crushing; in such mills, terracing shows the least advantage over the flat system because no practicable amount of terracing (except in rare instances) can provide an exclusively gravity flow for all unfinished products. On the other hand, ores containing only finely disseminated minerals can often be reduced at once to the final size by consecutive crushing operations, most of the unavoidable re-elevation being performed by scraper classifiers, and separation is made on tables or flotation machines requiring but little mill height. For a milling operation of this character, a gravity flow through the whole concentrating division of the plant can be obtained by a moderate amount of terracing; the re-elevation saved thereby, as compared with a flat mill, while of relatively small lift, is large in total volume, the pulp usually containing 75% or more of water. Methods of re-elevating ore, dry or in pulp, are described in Art. 6 and Sec. 18.

Re-elevation of water. Assuming water reclamation necessary, the advantage is with a low mill. A tall or terraced mill can sometimes utilize the tailing water from jigs treating sized or washed ore as wash water on tables at a lower elevation, but in general clarified water in large amounts is not obtainable until near the end of the concentrating scheme, and most frequently is not recovered until after it has left the mill at the lowest point. If ore is re-elevated by pumps, it must be accompanied by at least an equal weight of water, and may require three times that amount, or more, depending upon its coarseness.

Interest and amortization. The excess cost of a terraced mill as compared with a one-level mill of corresponding capacity should be taken into account in comparison of operating costs. The amortization charge per ton will be small for a mill of long life. An elaborate and expensive mill would be injudicious for a mine of dubious life. This explains the character of mill structures commonly erected in the Wisconsin and Joplin zinc districts.

Supervision of machines is greatly impeded when the millmen are compelled to walk up and down stairs; hence in a large mill, justifying the employment of specialized millmen, it is advisable to place as many as possible of the machines of one kind on the same level; in a small mill, as much as possible of the whole equipment should be on one floor, to insure equality of supervision. Facility of supervision not only fixes the number of millmen to be employed at a small mill, but may influence the tonnage and recovery attained. A mill using several dissimilar crushers, or operating a process requiring a variety of concentrating apparatus or involving extended use of hydraulic classifiers, will need more supervision than a mill of the same capacity using only ball mills and flotation. Any mill, however small, needs a certain minimum of supervision, while in another mill of the same type a much larger tonnage may often be treated with the same labor force. A large mill is justified in the installation of mechanical equipment for performing certain operations, such as collection of concentrate, which can be done more profitably in a small mill by hand labor.

Repairs and renewals are much simplified in a level-site mill, where workshops and the operating floor can be joined by a level traveling way or overhead crane.

Lack of working space on the ball-mill terrace was one defect of the ALASKA-JUNEAU mill; the ALASKA-GASTINEAU provides a shop on every terrace; at the UNITED COMSTOCK commodious shops serve every part of the ball-mill floor by track and crane (*114 J 846, 117 J 616*).

5. MATERIALS FOR MILL CONSTRUCTION

The durability of a mill building should bear an approximate relation to the expected life of the mine; any expense incurred for making the structure outlast the mine is wasted. The useful life of a mill cannot always be predicted, but during the development of any mine or group of mines up to the stage at which erection of a mill becomes justified, enough information should have been obtained to permit a reasonable estimate of the minimum tonnage likely to be available. The largest and most expensive mills are not undertaken until the factor of ultimate tonnage has been most carefully investigated.

Foundations. Concrete is almost universally employed, except at certain small mills on ground not likely to be heaved by frost, where wooden blocking is sometimes sufficient. Materials for concrete aggregate can be developed readily; waste rock from the mine is satisfactory for coarse aggregate provided fines are removed; sand and gravel are usually available locally, and any harmful clay or dirt can be removed by simple washing.

At ALASKA-GASTINEAU all the concrete was made with rock and sand provided by excavation of an underground storage pocket adjacent to the mill.

Concrete both for building and machinery foundations is designed today to obtain maximum strength through a combination of high-grade concrete (testing 3,000 lb./sq. in.) and adequate reinforcing steel. Retaining walls may have the customary batter of 1 or 1 1/2 in. per ft. on the outside face, or may be vertical, as at ANACONDA and SANTA BARBARA, depending on the wall design and location of the reinforcing steel. Concrete foundations for heavy vibrating equipment, such as stamp batteries and pneumatic steel sharpeners, are topped with semielastic pads to protect both machine and foundation; but jaw crushers, cone crushers, ball mills, etc., are bolted directly to the foundation by anchor bolts imbedded in the concrete and are grouted in place after leveling.

Concrete may be poured at temperatures down to 0° F., if proper precautions are taken to avoid freezing. Hot water and hot aggregate are used; and the ground, forms, reinforcing, and concrete are kept warm for 48 hr. by live steam discharging slowly from 3/4-in. pipe through 1/8-in. perforations every 18-in., the entire foundation being covered tightly with tarpaulins except during actual pouring. Calcium chloride (2 lb. per bag of cement) is added during mixing to cause rapid setting. Cost of heating ranges from $2 to $4 per cu. yd. depending on the shape and volume of the foundation. In subzero temperatures the danger of freezing increases sharply, with corresponding increase in cost of protection, to an extent which is quickly prohibitive.

Concrete foundations must be carried below maximum frost penetration to avoid ground heaving. In freezing weather, form stripping and backfilling must be performed very shortly after heating is completed, to prevent the ground under the concrete from freezing. If the backfill is frozen, it should be thawed and tamped into place.

Framework. Timber, steel, and reinforced concrete are the customary materials. Wood is the only material found in older mills, and it is still occasionally employed for framing large mills and nearly always for small ones. Wood has the advantages of: (*a*) lower cost per unit of weight and also, in most places, per unit of strength; (*b*) reduced amount of detailed designing; (*c*) quicker delivery; (*d*) cheaper erection, by less highly skilled and more easily obtained labor; (*e*) elasticity, as compared with reinforced concrete. Its principal drawbacks are inflammability and liability to decay, especially in floors and mudsills, which are unavoidably damp. Unless the entire structure is fireproof, however, a slow-burning frame is not an added hazard, and adequate ventilation and chemical treatment reduce decay to a negligible minimum.

Structural steel is the prevailing material for large permanent mills, such as BRITANNIA (1,426 tons of steel in a terraced mill covering a horizontal area of 56,400 sq. ft., or 51 lb. per sq. ft.), EAST MALARTIC, MCINTYRE PORCUPINE, KERR-ADDISON (244 tons of steel in a mill covering 18,400 sq. ft., or 26.5 lb. per sq. ft.), COPPER QUEEN, CHINO, KIMBERLEY, PANDA, SILVER KING, HOMESTAKE (SOUTH), UTAH COPPER, and the cyanide division of the UNITED COMSTOCK mill (441 tons of steel in a building of 75 ft. maximum height covering 2 1/4 acres, or 9.2 lb. per sq. ft. of area). In addition to being fireproof and durable (if painted properly), steel has the advantage of permitting longer trusses and wider spacing, thus reducing the necessary number of columns which occupy or obstruct useful floor space (66-ft. spacing both ways at UNITED COMSTOCK); the columns themselves can also be longer without requiring such extensive cross bracing as would be needed for a wooden structure of same height. Many of the heavy loads (up to 60 tons) commonly carried by cranes serving the crushing departments of modern mills could not be supported safely on any practicable timber structure. While steel structures call for more detailed designing than wooden frames, much of this work can be delegated to the steelwork contractors; many steel fabricators carry in stock or can quickly supply columns, trusses, or whole buildings to cover specified floor areas with a roof of given height. Bearings or hangers for

line shafts can be attached easily to steel beams by clamps; they are readily shifted and do not weaken the members by bolt holes, as is the case with wooden beams.

Reinforced concrete has not yet been widely adopted for structural framework, although it was used in the coarse-crushing, fine-crushing, and concentrating departments of the UNITED COMSTOCK mill (*114 J 846, 117 J 616*); in this instance, owing to the easily available aggregate for concrete and the relatively high cost of structural steel, reinforced concrete was estimated to be nearly 20% cheaper than steel. Estimates of wooden construction were 30% lower than for concrete, but the saving on insurance within 3 yr. was enough to offset this difference. The cost of the structural concrete work, excluding 15,000 cu. yd. of foundation and retaining walls, was: Concrete, 132 cu. yd., $1,980; reinforcing steel, 21,600 lb., $1,050; forms, 9,500 sq. ft., $1,700; total, $4,730, or $35.83 per cu. yd. For all-steel construction, the corresponding cost for 106,020 lb. of steel, at 8¢ erected, was estimated at $8,481. In a mill of reinforced concrete, special attention must be given to the support of oscillating machinery, on account of the severity of the stresses caused by continuous vibration in one direction.

Walls may be tile, brick, cement block; gunite, either on metal reinforcing or as an added coating; corrugated iron, corrugated asbestos-cement; wood sheathing with a variety of outer covering, or fiberboard. Corrugated iron, galvanized or asbestos coated, is the commonest material. A wooden frame is usually sheathed with boards, to which corrugated iron is nailed over a layer of building paper. On a steel frame the corrugated sheet is attached by bolts, clamps, or wire, with no wood sheathing; this construction is fire-proof. If it does not afford sufficient protection against cold, the interior can be coated with gunite, applied against woven-wire or expanded-metal reinforcement, with as much insulating material as desired. Tile is light and warm; tile and brick and all-brick have long life.

The walls of the UNITED COMSTOCK cyanide section are composed of an outer layer of No. 24 corrugated and an inner layer of No. 28 plain galvanized steel, separated by two thicknesses of tar paper (Table 27). At the N. Y. ZINC Co. 5-story mill at Edwards, N. Y., the walls are hollow tile, and the equipment is entirely supported by a steel framework having no connection with walls (*116 J 95*). The tall, steel-framed RICHARD mill has hollow-tile walls for the lower half of its height, and asbestos-coated corrugated iron for the upper half (*115 J 973*). MCINTYRE PORCUPINE is largely hollow tile; large buildings at NORANDA are tile, small are mostly brick; both tile and brick are used at INTERNATIONAL NICKEL at Copper Cliff.

Tile walls are much improved in appearance by an outer coating of mortar or GUNITE; when this finish is intended, the tile should be placed rough side out. The best mixture for applying with a cement gun is four parts clean sharp sand to one part cement; in a dry climate, the sand may be increased to six parts. The outer face of the tile must be thoroughly moistened before the mortar is applied, but no reinforcement should be necessary, as would be required with a wooden wall. When applied with a cement gun (*Bul. 114, Cement Gun Co.*) 1 bag of cement and 3 cu. ft. of sand will cover 22 sq. ft. with a layer 1 in. thick. A force of eight men at $41 per day (including the operator of a portable compressor, which may not be necessary at an established mine plant) can average 1,300 sq. ft. of gunite per day. The cost of a cement gun, not including a portable compressor, ranged (1923) from $1,325 to $1,565, corresponding to free-air capacities of 100 and 225 cu. ft. per min. respectively.

Corrugated asbestos-cement board, such as Johns-Manville TRANSITE, has been used in the same way as corrugated iron, but is more easily damaged. FIBERBOARD such as TEN-TEST (1 in. thick) has been used where initial cost, light weight, and some insulation have been controlling factors, but it must be painted thoroughly inside and outside, and the joints must be covered carefully as protection against moisture. ONTARIO REFINING Co. weatherproof storage buildings, 400 ft. long, at Copper Cliff have walls covered with Transite clipped to steel framework. PARKHILL and THOMPSON-CADILLAC mills in Ontario have fiberboard walls.

Where protection against low temperature is important, as in Canada, the most usual wall construction is 1-in. wooden sheathing covered with waterproof building paper and an outer weatherproof covering of rock-faced asphalt roofing, asbestos sheeting, or stiff composition shingles. For additional insulation a 1/2-in. thickness of fiberboard may be placed outside the building paper, covered with building paper and the customary outer weatherproof facing. WRIGHT-HARGREAVES mill at Kirkland Lake and CONIAURUM mill at Schumacher have fireproof composition shingles and steel frame building. SLADEN-MALARTIC mill at Malartic and ALDERMAC mill at Arntfield have wooden walls covered with asbestos sheets. Smaller mills usually use rock-faced roofing as outer covering because of lower initial cost.

A comparison of estimates of costs and heat-insulating characteristics of different types of walls for the UNITED COMSTOCK cyanide building is shown in Table 27.

Table 27. Costs and heat-insulating characteristics of walls

	Cost per square foot, cents	Boiler horse-power to heat plant
Plain galvanized corrugated sheet	14.0	220
Gunite, 1 1/2 in., on metal lath	19.6	116
Hollow clay tile, 4-in.	35.0	93
Galvanized corrugated steel outside, plain galvanized inside, 2 layers of tar paper between	19.5	125
Wood sheathing, tar paper, galvanized corrugated steel	24.5	93

Roofs. Corrugated galvanized iron is the commonest roofing material. In a cool climate, a board sheathing is almost indispensable to prevent condensation and dripping of moisture; the corrugated sheet is fastened down to this by lead-washered nails. CORRUGATED ASBESTOS-CEMENT SHEET may be used to replace corrugated iron; it has better insulating qualities but is more brittle. Asbestos materials are durable without paint, and they resist fire. Other roofs consist of two elements, *viz.*, a weight-carrying support and a weatherproof cover. For the former, light-weight pre-cast concrete slabs (HAYDITE) are durable and easily designed to rest on steel purlins; GYPSUM SLAB may be poured in place on mesh reinforcing; 2-in. tongue-and-groove or 1-in. shiplap are carried on wooden joists or on nailing strips on steel. The weatherproofing layer is of two types: (*a*) standard three- or four-ply asphalted felt for flat slopes, (*b*) rock-faced asphalted felt laid over one layer of impervious building paper for steeper slopes. For insulation to prevent condensation, 1-in. fiberboard, mopped up on all sides with asphaltic tar, is placed under the weatherproof cover.

BRITANNIA MILL required 96 tons of corrugated sheet for a total roof area of 58,100 sq. ft. SMUGGLER UNION mill in Colorado (cold winters with heavy snow) has a roof of No. 22 corrugated iron laid on one layer of 1/16-in. asbestos sheet and two layers of tar paper; the inside is gunite on woven-wire reinforcement. The roof over the cyanide department of UNITED COMSTOCK (96,400 sq. ft.) is made of 1 3/4-in. Oregon pine, tongued and grooved, covered with No. 20 corrugated sheet. The roof of the KIMBERLEY steel-framed mill (77,000 sq. ft.) is composed of 2 × 4-in. timber on edge laid face to face and covered with felt, tar and gravel (*115 J 244, 116 J 453*). At ONTARIO REFINING Co. the roof is gypsum slab poured in place with a built-up tar and felt covering. SLADEN-MALARTIC has a 2-in. layer of rockwool between upper and lower layers of 3/4-in. B.C. fir shiplap, covered with a 3-ply built-up asphalt-felt roof. KERR-ADDISON, EAST MALARTIC, and UCHI mills have roofs composed of 3/4-in. shiplap, 1-in. fiberboard, and 3-ply felt and asphalt built-up roof, for severe winter cold.

Snow, in addition to its dead weight of 12 lb. per cu. ft. (*Trautwine*), interferes with roof lighting and may cause damage by sliding in heavy masses. This may be prevented by: (*a*) snow guards; (*b*) giving the roof sufficient slope (30° or more) to cause the snow to slide soon after it falls (ALASKA-JUNEAU installed salt-water sprays to flush the snow off the roofs as fast as it fell); (*c*) making roof so nearly level that snow can not slide (as at HOMESTAKE SOUTH mill). According to *Kidder*, metal roofs in the Rocky Mountain and northwestern states should be designed for the following snow loads per sq. ft. of roof surface: 1/2-pitch, none; 1/3-pitch, 10 to 12 lb; 1/4-pitch, 20 to 25 lb.; 1/5-pitch, 27 to 37 lb.; 1/6-pitch or less, 35 to 45 lb. UNITED COMSTOCK roof, with an unbroken slope of 20° (1/3-pitch) was designed for a snow load of 40 lb. per sq. ft. and a wind load of 20 lb. per sq. ft.

Windows and skylights. Daylight is of the utmost importance in practically every department of a concentrating mill. It is easily provided in a tall structure, the walls of which can be composed of glass to a large extent, as in anthracite breakers. A terraced mill can be amply lighted from its sides, and also by vertical windows in the breaks of the roof.

The steeply terraced BRITANNIA mill has 22,300 sq. ft. of windows for lighting a horizontal area of 56,400 sq. ft. (*29 MM 204*).

A low, flat mill can be lighted by skylights in the roof, subject to interference by snow and probability of leakage unless constructed with special care; a turreted or sawtooth roof with windows in all available vertical spaces is frequently used for industrial plants and should be equally useful for ore-dressing plants.

Fenestra steel sashes have been installed in large numbers at UNITED COMSTOCK, HOMESTAKE, and numerous other mills with both steel and wood construction. At COPPER QUEEN the windows are glazed with ribbed glass, for diffusion of sunlight, and the skylights are of RUBBER GLASS. This material is used for skylights in many other mills in the Southwest, where snow is unknown, rain not abundant, and the sunlight so intense as to make the imparted yellow tint agreeable.

Windows and skylights may also form an essential part of the ventilation scheme for a mill, particularly in hot climates where air circulation is desirable to reduce humidity. Glass should be readily accessible for cleaning, and sufficiently protected to avoid careless breakage.

Floors. Wood and concrete are used indiscriminately in mills of either wood or steel construction. A wooden floor in the wet-concentrating section of a mill should be tight, to prevent loss of concentrate, and should preferably be laid with green timber, to avoid warping. Concrete floors are usually poured in place. Two- to 4-in. thickness of concrete poured over tight wooden floors produces a smooth impervious surface at little cost. It may be reinforced with expanded metal to prevent cracking. Concrete floors are preferable in cyanide mills and other plants where floors are washed down to recover spilled values.

UNITED COMSTOCK used pre-cast concrete slabs supported by steel frames. At the steeply terraced mills of the SILVER DYKE, NATIONAL COPPERMINES, and UTAH CONSOLIDATED mills reinforcement was obtained by discarded hoisting rope in lengths running unbroken from the highest to the lowest floor, passing horizontally through every floor and downward through the intervening retaining walls, thus tying the latter securely together.

The SLOPE of floors in the wet parts of a mill should be sufficient to permit rapid drainage; 1/4 and 1/2 in. per ft. are usual, the latter preferred. Slopes up to 2 in. per ft. have been used to permit launders to be laid on the floor, but this is unnecessary and makes walking unsafe. Duckboard walkways should be provided on concrete, particularly in wet sections, for both comfort and safety. If dry floors are to be cleaned by sweeping, they require no slope; but washing down floors is so easy and effective that concrete floors, even in the dry section, should be graded to permit it.

Floors should be kept as clear as possible of pipes and launders to permit easy walking and cleaning and free drainage. If it is planned to wash down floors, a sump should be provided to collect the water for pumping or other disposal. Where ground contour permits, it is considered good practice to install large sumps with a capacity sufficient for the entire contents of a thickener tank or agitator. Such sumps were constructed at KERR-ADDISON and SLADEN-MALARTIC.

Painting is done both for protection against corrosion and to assist lighting. Inside paint should therefore be of a light tint. Black corrugated iron should be protected by at least two coats of paint, renewed at frequent intervals. Galvanized iron does not usually require paint protection, although it is subject to rapid deterioration anywhere in the vicinity of a smelter. Paint does not adhere well to new galvanized iron, but after the metal has been exposed for 2 or 3 yr. any good paint will adhere firmly. Highly effective rust-resisting and cyanide-resisting paints have been developed for the protection of steel frames and tanks. Aluminum paint is being used moderately. Wooden buildings seldom are painted inside, although a coat of whitewash on the interior of a wooden mill building reduces the fire insurance rate in Canada. It is difficult to make whitewash adhere firmly enough to resist loosening under continuous vibration, but it can be applied successfully to wooden buildings by an airbrush following a glue sizing coat. An airbrush is useful for applying oil paint also.

Table 28. Square feet covered per gallon of paint

	On wood	On metal	On concrete
Priming coat	300–400	500–700	150–250
Second and third coats	400–600	700–800	300–400
Spray painting, first coat	275–350		
Second and third coats	500		

Cost of spreading paint is about double the cost of the paint. Normal paint consumption is given in Table 28.

First coat of spray painting is equal to 2 coats of brush painting. Spray painting, cold-water white, etc., 1 lb. covers 25 sq. ft.

6. ARRANGEMENT OF MILL EQUIPMENT

The grouping of mill equipment should aim to satisfy the following requirements: (*a*) mechanical transfer of feed and products by the shortest and most direct routes, utilizing gravity flow so far as economically practicable (see Art. 4); (*b*) convenience of superintendence (see Art. 4); (*c*) economical connection with driving power (see Art. 7); (*d*) facility of repairs (see Art. 9); if possible, provision should be made for by-passing any piece of machinery undergoing repair, to avoid complete suspension of operations; in a small mill, without duplicate equipment, this may not be possible; (*e*) facility of enlargement or remodeling (see Art. 4); (*f*) isolation of dust-making operations, with or without arrangements for collecting the dust (see Art. 8).

Grouping in plan. Dimension sheets giving over-all dimensions of the individual pieces of ore-dressing equipment are usually obtainable from the makers. The additional necessary allowance of floor space between and around the machines composing a single group should provide for: (*a*) walkways for inspection and adjustment of machinery; also, in some cases, for manual disposal of concentrate by wheelbarrow or tram car; (*b*) working space for making repairs with minimum amount of carriage; (*c*) launders, chutes, or conveyors for the several products of the operation; (*d*) motors, in case of individual drives, with speed reducers when required; (*e*) elevators or pumps, possibly serving other groups of mill equipment.

Jigs, tables, pneumatic flotation cells, and other equipment to which a sufficient amount of attention can be given from one side, are often consolidated into pairs, or blocks of four, mainly to facilitate feeding and to combine discharges, but also to economize floor area. Ball, pebble, or rod mills are usually set as close as possible to a sand-slime separator. Screens and hydraulic classifiers seldom require special allowance of floor space, since they can usually be supported overhead. Spacing of coarse crushers is frequently determined by the dimensions of the bins from which they receive their feed or to which they deliver

Table 29. Total floor areas of typical mill buildings

Mill and location	Capacity, tons per 24 hr.	Process	Segregated areas, sq. ft. per ton per 24 hr.							Total area per 24 hr.-ton

a Does not include r.o.m. bin.
b Does not include mill bin.
c Does not include conveyor galleries.
d Includes sorting.
e Includes space for expansion to 1,500 tons capacity.
f Includes space for expansion to 175 tons/24 hr.
g Includes all bins.

rather than by the amount of floor space they actually require. Table 29 gives total floor area of representative mills.

Grouping in vertical relation. The difference in elevation between the points at which a given piece of apparatus receives its feed and discharges its products is most important from the standpoint of mill design, since it is this dimension that fixes the position of the machine with respect to the "stream line" of the mill. Over-all vertical dimensions are needed for placing foundations and making allowance for head room; the latter should make due provision for hoisting out parts of machines requiring replacement.

Chutes and launders. (See Sec. 18, Arts. 15, 16.) In general, a chute for nominally dry material should have a slope of not less than 45°, to avoid choking in case of accidental or temporary wetting. A launder that proves to have insufficient grade can be corrected, if it is impossible to increase its slope or if inadvisable to increase the proportion of water, by diminishing its width or by introducing liners of smooth material with low coefficient of friction. Rubber, both of crude crepe and vulcanized varieties, is used rather frequently as lining material for launders subjected to hard service; in spite of its higher cost per lb., it is usually cheaper than steel or chilled iron per sq. ft. of surface, and compares favorably with those materials in withstanding wear. Locally made concrete slabs are usually much cheaper per sq. ft. than iron. In places where sufficient gravity flow is not easily obtainable, as in collection of concentrate or tailing from a long line of jigs or tables, a shaking launder on a grade as low as 3/8 in. per ft., suspended by flexible wood strips and oscillated by an ordinary table head-motion at one end, has been found useful at New Jersey Zinc Co. and Santa Barbara (*112 J 1050*). Another method applicable to jig tailing is to dewater on a screen and deliver to a horizontal belt conveyor. Use of pipes as substitutes for launders is increasing. They are installed to permit turning at intervals to compensate for wear.

Launder slopes. The slopes given in Table 30 are suggested as working limits for rectangular wooden launders conveying average ores of pyrite, zinc, and copper, with concentrating ratios between 4 and 20 to 1, and dilutions of not less than 2 water to 1 ore. See also Sec. 18, Art. 16.

Table 30. Average slopes for launders

Jig and table mills	Inches per foot	Fine-grinding and flotation mills	Inches per foot
Trommel product:		Sands, 20% moisture, classifier to	
> 20-mm	5–6	tube-mill:	
20~10-mm	4–5	30-m	4–6
10~5-mm	3–4	80-m	3–4
5~2 1/2-mm	2–3	Tube-mill discharge to classifier:	
< 2 1/2-mm	1 1/2–2	30-m	2–2 1/2
Table feed, 20-m	1 1/4–1 1/2	80-m	1 1/2–2
Table tailing, 20-m	1 1/2	Classifier overflow to flotation:	
Table middling, 20-m	1 1/2	48-m	1/2–3/4
Table concentrate, 20-m	2 1/2	80-m	1/4–1/2
Tailrace, mixed sizes	3/8–3/4	Flotation concentrate	2–3
		Flotation tailing	1/4–1/2
		Tailrace	3/16–1/4

For zinc-lead and iron-oxide ores of low concentrating ratio, the launder slopes would need to be probably 25% steeper than those stated above.

Cost of launders. Estimated factory cost (1938) per lin. ft. of knocked-down launders made of 1 5/8-in. surfaced fir with tongue-and-grooved joints, and nailed-up frames at 4 to 6-ft. intervals, is as follows: 5 1/2 × 4-in., $0.50; 11 × 8, $1; 16 1/2 × 12, $1.50; 22 1/2 × 16, $2; 34 × 20, $3. Cost of assembly on the job should be added. From the figures in Table 31, relating to reconstruction of the Phelps-Dodge Morenci mill in 1924, it is seen that the labor cost to install $1 worth of unfabricated launder material ranged from $1 to $1.25. In this mill, only 14.4% of the whole launder system was over 16 in. wide.

Elevation of ore in transit through a mill is practically unavoidable, even on steeply terraced sites; on flat sites, elevators or sand pumps constitute a large and expensive part of the mill equipment, beside requiring close attention to maintenance. Structural details of inclined belt or pan conveyors, belt-bucket or chain-bucket elevators, sand pumps, centrifugal pumps, and suction pumps for ore pulps are given in Sec. 18.

Proper selection of elevating equipment depends less upon relative power efficiency than upon reliability, maintenance, cost, and convenience, since the power consumed is comparatively small (1 to 5% of total mill power).

In dry-crushing plants, the choice lies between bucket-elevators, belt conveyors, and pan conveyors. Mechanical efficiencies are approximately 60%, 50 to 70%, and 20 to 35% respectively. For wet pulps, bucket-elevators and pumps are used. With the high cir-

culating loads of modern ball-mill practice, a wheel elevator, consisting of a large pulley with standard buckets attached, is sometimes used for low lifts; or a scraper, or screw conveyor may be used for sand return, if the horizontal carry exceeds the capacity of a wheel.

Centrifugal sand pumps are generally preferred, since they are more readily accessible and may be piped almost directly to the discharge point; the drawbacks to their use in such service are excessive wear with consequent lost time, but wear is minimized by rubber lining.

Inclined belt conveyors (see Sec. 18, Art. 6) for initial delivery of ore to the mill are discussed in Art. 1, and those for disposal of tailing in Art. 4.

When a belt conveyor is used to gain elevation, the horizontal displacement is from 2 1/2 to 3 times the height gained (18 1/2–22°), and considerable mill room or outside housing is required. Conveyors are ideal for distributing crushed ore into long bins or to a series of bins or tanks. For wet ore in cold climates, it may be necessary to reduce slope below 4 in 12 (18 1/2°) to prevent sliding.

Table 32 gives data required for selection of a conveyor. Distribution along the run of a conveyor system is usually done on a level section, by means of: (*a*) tripper on rails, hand-propelled or self-propelled with automatic reversal; (*b*) shuttle conveyor on frame or rail, discharging over end pulley, hand-propelled at occasional intervals; (*c*) scrapers on the belt, suitable for sticky materials but usually unsuitable for ore on account of high wear.

Inclined pan conveyors (see Sec. 18, Art. 7) are most used for elevating crude ore in lumps of such size (say 4-in. and over) that they would be injurious to rubber belts; incidentally they may serve as feed regulators for coarse crushers.

At United Comstock (*114 J 846, 117 J 516*) a 48-in. Stephens-Adamson pan conveyor 91 ft. long and rising 30 ft. (20°), driven at 9 to 15 ft. per min. by a 20-hp. variable-speed, slip-ring motor, carries 125 tons of mine-run ore per hr. At the Copper Queen concentrator are two 54-in. pan conveyors in parallel, each capable of carrying 1,800 tons of 8-in. ore per hr. (250 tons normal rate); length, 61 ft.; rise, 21 ft.; slope, 20° 10′.

Table 32. Belt conveyors

Belt, width by plies	Max. size, in. Sized	Max. size, in. Run-of-mine	Tons per hr. @ 100 ft. per min.	Slope from horizontal: — 0°	1/12 5°	2/12 9 1/2°	3/12 14°	4/12 18 1/2°	Hp., max. @ 100 ft. per min.	Max. belt speed, ft. per min.

	3	40	10	18	60	0.8

a If it is desired to use heavier belt than the tabular value, in order to prolong life, head-pulley diameter should be changed correspondingly. To calculate the new value, first calculate a new maximum lift on the proportion:

$$\frac{\text{New maximum lift}}{\text{Tabular maximum lift}} = \frac{\text{New plies}}{\text{Tabular plies}}$$

Next determine percentage proportion of actual lift to new maximum lift, and estimate pulley diameter from note *c*.

b Tonnage and horsepower based upon buckets:
- 25% full of dry material, 100 lb. per cu. ft.; or
- 50% full of dry material, 50 lb. per cu. ft.; or
- 40% full of water or somewhat smaller amounts of pulp.

c For less than max. lift, diameter of head pulleys may be as follows:
- 70% max. lift, 5 in. per ply; 50% max. lift, 4 1/2 in. per ply;
- 25% max. lift, 4 in. per ply; 10% max. lift, 3 in. per ply.

d Speeds are for centrifugal discharge.

Bucket elevators (see also Sec. 18, Art. 12) are used for dry ore when the lift required for a given horizontal run is more than can be obtained with a simple inclined conveyor, and the elaborate zigzag of a multiple conveyor system is undesirable. For coarse wet pulps they compete with centrifugal sand pumps. In such duty they have the advantage of nonclogging and less wear, but they are more expensive to install, they must lift several feet above the discharge point, they must run substantially vertically in order to utilize reasonably full bucket volume, they occupy much floor space and mill volume, and much of the repair work must be done at the top. As a consequence, most designers install them only when use of a pump threatens almost certain trouble from clogged lines. For thin pulps of fine ore, pumps are substantially always used in preference to elevators. It is important to provide means for emptying the boot of an elevator when repairs are needed; such means should be so placed that the discharged material can be sluiced or easily transferred by other means to an adjoining elevator.

Belt-bucket elevators for wet work have the advantage over chain-bucket elevators of requiring no difficult and expensive lubrication and of having fewer wearing and friction-producing surfaces. The capacity of a given belt, however, is limited by its adhesion to the head pulley; this can be augmented by a wrapping of less slippery material around the pulley. Table 33 gives data necessary for selection of belt-bucket elevators for either wet or dry service.

Chain-bucket elevators (Sec. 18, Art. 12), in spite of their multiplicity of wearing and breaking elements, can be used satisfactorily for dry work but must then be lubricated with heavy grease to minimize the effect of grit; their capacity is limited only by the size of bucket that can be supported. Certain types have a pronounced advantage in being able to receive or discharge at a number of points in their travel, thus combining the functions of elevator and conveyor.

In one 250-ton mill, a single Peck conveyor-elevator was devised to perform all the following operations: (*a*) receive crushed ore *via* belt conveyor from a sampler; (*b*) elevate and deliver this ore, at will, into smelter bin, mill bin, storage bin for any class of ore (with the aid of a distributing belt conveyor), or bins for doubtful ore (pending assay); (*c*) withdraw doubtful ore from bins and deliver to smelter, storage, or mill bins; (*d*) withdraw ore from any storage bin (with the aid of a belt conveyor) and deliver to smelter bin or mill bin. See also UTAH APEX, p. 20–42.

Sand pumps. (See Sec. 18, Arts. 17, 18.) Centrifugal pumps for elevating gritty pulp must be specially lined, and even this affords little protection to the shaft, which is invariably a source of trouble and weakness. Introducing water under pressure around the shaft is a partial remedy but is not reliable and may be objectionable because of increased pulp dilution.

Dredge-type pumps with metal liners are used to some extent, but at considerable liner and "time-out" expense, and, when soft packing is used, with packing and shaft troubles. Pumps in which the rubber is vulcanized onto the shell and/or runner are being used increasingly. The Wilfley pump, which has a centrifugal seal and automatic check for sealing the shaft at shut-downs is most used, but, having no suction, requires a surge box or its equivalent to give a 3- to 4-ft. pressure head.

At the Clifton mill of ARIZONA COPPER Co., an Aldrich plunger pump, specially designed as to valves and plunger clearances, was used to dispose of table and vanner tailing. At MAGMA COPPER Co., all mill concentrate (5% >20-m., 63% <200-m.), derived about equally from tables and flotation, is pumped in the form of a thickened pulp (70% solids) to filters at the smelter, which discharge cake directly into the smelter bins, thereby dispensing with at least one handling (*J. W. Thompson, PC*). The pipe line is 4 in. diameter, 2,760 ft. long, and rises to height of 92 ft. near its middle point with slopes of 7°. No trouble has been experienced from sedimentation so long as the pulp consistency is held at 70% solids. A 4-in. Wilfley pump, driven at 1,600 r.p.m. by a 75-hp. motor, delivers 165 g.p.m. of this pulp, equivalent to 60 tons solids per hr. The operating costs per ton of concentrate (dry) in 1925 were: repair parts, 3.00¢; labor, operating, and repairs, 1.94¢; power, 0.60¢; total, 5.54¢.

Air lifts (see Sec. 18, Art. 21) for elevating ore pulps in process are satisfactorily employed in the NEVADA CONSOLIDATED, CHINO, RAY, NEW CORNELIA, and COPPER QUEEN mills, and in the older types of cyanide plants.

Skips are used for elevating roll products to screens at two points in the intermediate-crushing department of the ALASKA-GASTINEAU mill (*63 A 488*). The product from the primary rolls, set at 1-in., is hoisted in four skips of 5-ton capacity; that from the secondary rolls, at 10-m., in ten skips of the same size. The lift is 100 ft. in both cases. The skips are operated automatically and in counterbalance by a 75- to 135-hp. hoist motor for each pair; plow-steel rope is flat, 3/8 × 5-in. The loading gate is operated by a compressed-air cylinder controlled through a 3-way valve actuated by the descending skip; high-pressure water can also be used for operating the gate. Loading time is governed by an oil dashpot, which also throws the motor switch. Loading takes 11 sec., and the complete cycle for two skip loads is 1 min. 50 sec. The cost of operation compares favorably with that of dry elevators; maintenance is 0.9¢ per ton milled.

7. DRIVING POWER FOR MILLS

Individual power requirements for commonly employed machines, operating under stated conditions, are given in connection with the descriptions of the various machines. Tables 34 and 35 give the total motive power (installed or used) at several mills of representative types.

Table 34. Power consumption at typical mills

a *I.C. 6792.*

Line-shaft drives are used at small mills operated from a central power unit and at large motor-driven mills operating long blocks of similar machines having relatively small power requirements. It is substantially impossible to avoid a certain number.

Installation of line-shaft drives. For the elements of design, refer to mechanical-engineering handbooks (Kent, Marks, etc.; see also *107 J 1182*). The following general

suggestions refer particularly to ore-dressing works. (*a*) Shafts should have a wide margin of strength above that required for transmission alone; this is to provide against abnormal loads on pulleys due to shrinkage of damp belts and excessive shortening of belts to take up slack. (*b*) Pulleys, couplings, and clutches should be closely adjacent to bearings; the end of an oiled bearing, however, should lie 1 to 2 in. outside the nearer edge of an adjoining pulley, so that oil drippings will not fall on belt or pulley. (*c*) Hangers with ball-socket journal boxes are as satisfactory as pillow blocks for shafts of moderate sizes, up to 2 $^7/_{16}$ in. Larger shafts should be carried in pillow blocks; and for extra heavy service, a shaft should be mounted near the ground, on concrete piers if possible. (*d*) Ball-socket, or other self-aligning pillow blocks and journal boxes should always be installed for long shafts, and preferably also for short ones. (*e*) Ring-oiling journal boxes are satisfactory for general service; roller or ball-bearing journals are best for heavy duty; in dusty places, heavy-grease lubrication or grease-packed sealed bearings should be used. (*f*) Leather belts are admissible only in permanently dry places. Canvas belts deteriorate with moisture and lack pliability in large sizes. Rubber-covered belts give the best service in all parts of a wet mill; the most satisfactory weights are: 4-ply for 4- and 6-in. widths; 6-ply for 8- to 12-in.; 8-ply for 18-in. (*g*) Vertical belts should be avoided. Quarter-turn belts are admissible in sizes up to 8-in. and are unavoidable in rare instances. The minimum length between centers for belts without tightening idlers should be five times the diameter of the larger pulley. (*h*) Tightening idlers give good service, when needed, but require endless belts, since no form of lacing or coupling has proved satisfactory in this service; endless belts of leather can be spliced by gluing on the premises (*107 J 1132*) but endless rubber belts can be made only at the factory. (*i*) Chain drives or V-belts are useful for transmissions too short-centered for flat belts or where the desired speed ratio would require too small a pulley at one end; also for transmitting small power at low speed in dusty places. Their efficiency is high, and as they require no tension on the slack side, the journal friction at both ends is less than that caused by a short, tight belt.

Table 35. Installed horsepower at cyanide mills

Plant	Process	Tons per 24 hr.	Installed horsepower									
			Crushing and handling	Grinding and classifying	Thickening	Filtering	Agitating	Precip'n	Tailing disposal	Misc.	Total	Per 24 hr.-ton

a 75% <200 mesh.

Stopping and starting from line shafts. Tight-and-loose pulleys with a belt shifter are suitable for machines of relatively small power requirements, up to 25 or 30 hp., with belts up to 8 in. wide. Dental or jaw clutches for throwing the load on a moving shaft can be used safely for speeds under 30 r.p.m. Clutch pulleys are unsatisfactory where their power is likely to be unutilized for considerable periods, owing to rapid wear of the bushings; this is particularly objectionable in case of a stationary pulley riding on a moving shaft, since the wear will then be eccentric. Friction-clutch couplings, of band, jaw, or disk types, connected with a short jackshaft, or with a quill, and supported by adequate journal boxes, are much better than clutch pulleys. The quill system is well adapted to driving a row of machines from a long main shaft.

Mechanical transmission in some form is necessary between the motor and the driven machine. The type selected depends upon the nature and source of power, the nature and operating requirements of the driven machinery, speed, starting characteristics, and cost.

Long belts are efficient, but they may occupy space needed for other purposes. The belt span should not be less than five times the diameter of the larger pulley, and the more nearly horizontal the better; inclinations up to 60° are allowable.

Short belt, with a tightening idler, permits the motor to be placed at either side or above or below the driven pulley, with a clear distance as short as 2 or 3 ft. between faces of pulleys; endless belt is practically unavoidable. V-belts are much better.

Slack belt, with a swinging tension idler, was formerly the standard method of driving individual stamp batteries operated by a single line shaft; this practice is now becoming obsolete, modern stamp mills using an individual motor for every five or ten stamps.

Chain drive is as efficient mechanically as a short belt with tightener and has the advantage of producing less journal friction in both sprocket shafts. The shaft must be accurately aligned and so mounted that the chain may be tightened. Wherever possible, vertical chain drives should be avoided and the machines should be mounted so that the chain may be conveniently taken off and replaced without undue loss of time. For this reason the sprockets should not be too close to walls or other machines.

Spur gearing is an accepted method of driving tumbling mills. Owing to the impossibility of preventing some longitudinal motion in the mill, which will be transmitted to the pinion shaft, a motor cannot safely be rigidly connected to the shaft, but must drive through a flexible coupling; or by belt or chain, if further reduction of speed is desired.

Herringbone gear is more expensive than spur gears, but permits larger speed reduction and is sufficiently more efficient in power transmission to pay for itself easily in tube- and ball-mill drives where the motor is direct-connected to the pinion shaft.

Worm gear with high ratio of speed reduction is applied to such slow-moving apparatus as thickening tanks and, with a lower reduction ratio, to head motions of unit-driven tables and for conveyors. For driving inclined conveyors and all forms of bucket elevators, worm-gear drive avoids the necessity of safety devices to prevent back travel on stopping.

Bevel gears are found chiefly in gyratories, Chilean mills, trommels, and old-type M.S. flotation cells; they are usually a source of annoyance, and are to be avoided wherever possible.

Speed reducers are efficient and convenient, and are in everyday use. Spur or herringbone reducers are often interposed as a direct connection between the motor and the main-gear pinion shaft for driving tube and ball mills. Motor and gearbox should be mounted and aligned on a common base plate with a flexible coupling between gearbox and pinion shaft. Worm-and-wheel speed reducers are available for smaller powers and for high-ratio reductions; they are convenient for elevator and conveyor head drives. A flexible connection either in the form of a coupling or a chain drive is also necessary. Any type of gearbox used should be totally enclosed, dustproof, and oil flooded.

V-ropes. These represent the greatest single advance in belt transmission of power in recent years. They consist of grooved sheaves, with a suitable number of fabric and rubber "ropes" or belts of a cross-section to fit the grooves. They permit considerable speed reduction, and are efficient at short center distances. Under severe load conditions the ropes may slip; this constitutes a safety factor to prevent serious damage from overload.

Power transmission units (GEARED MOTORS) consist of a combined totally enclosed and oil-flooded train of gears, and an electric motor; they are frequently used for driving conveyors, elevators, diaphragm pumps, and other low-power machines. Geared motors are gradually replacing slow-speed motors in combination with individual speed reducers for sizes up to 75- and 100-hp.

Pivoted motors with flat-belt drives, such as the American or Rockwood, are pivoted or hinged so as to provide uniform tension on the belt under varying conditions of load. Such drives, like V-rope drives, can be operated on short centers, are suitable for various sizes of machinery, and provide a good safety factor should the driven machine stall for any reason, since the belt usually runs off the driven pulley.

Direct connection between driving and driven machine makes a compact and efficient arrangement. Proper flexible couplings between the two shafts must be provided to reduce shocks due to sudden loads, and to correct any small errors of alignment. Such drive is more troublesome to change than other types when the driven speed must be varied. Direct connection is particularly applicable for such high-speed machinery as centrifugal pumps, fans, and blowers.

Individual motor drives are almost universally installed at modern mills, for all classes of equipment except tables and other small-power apparatus which can be closely grouped into rows or blocks and easily driven from line shafts. The advantage of individual drives is mainly their ease of installation; they make accurate alignment unnecessary, avoid overhead supports for line shafts, and are easy to maintain. For driving heavy equipment, individual motors offer the same advantages, with the added economies introduced by operating at higher efficiencies and power factors.

Motor characteristics. Large ore-dressing plants in North America operate, almost without exception, with alternating current. This form of energy is generally available and the apparatus is cheaper and simpler than direct-current apparatus. Direct current is utilized for special operations such as crane haulage, electrolytic refining, and battery charging and when accurate adjustment of motor speed is desired; it is obtained from a separate generator, a motor-generator set, mercury arc, or other form of electronic rectifier. For outside haulage, standard voltage is usually 550; inside, 250 or 275; for power and special applications and for battery charging, the direct-current generator can be designed to give any voltage which best meets local conditions.

Frequency has been standardized at 60-cycle for most of the United States and 50-cycle for the rest of the world. There is some economy in transmitting and transforming 25-cycle current, but it is unsuitable for lighting without frequency increase. Old government plants and a number of private users with large power units are on 25 cycles.

Static-electricity apparatus and machines calling for speeds higher than 3,600 r.p.m. usually are supplied with high-frequency current from special motor-generator sets. Unidirectional currents for precipitation are supplied by rectifiers.

The 60-cycle motors have been standardized in the United States as to shaft sizes, bases, and other external dimensions, so that interchange between most makes is simple and convenient. Some adjustment in sizes by a plant designer is advisable to permit replacement from idle motors in case of a breakdown.

Phase. Practically all motors larger than 1/2-hp. in American mills are on three-phase current. The small motors used on samplers, reagent feeders, and the like are preferably single-phase, wired for either 110 or 220 volts. Three-phase motors in the same sizes cost more, and delivery is slow. The UNIVERSAL, a small motor, is wound for either 110 or 220 volts to operate on a-c. or d-c. current; it is used generally on portable tools. Speed may be as high as 15,000 r.p.m. without regard to frequency, but it falls off rapidly with increase in load.

Table 36. Standard a-c. voltages for various uses

Volts	Phases	Applications
110	1	Lights, portable tools, motors 1/2 hp. and less.
220	1	Small machines, 2 hp. and less.
220	3	General city industrial installations.
440	3	Motors 1–25 hp., or larger.
2,200 and higher		Induction motors 25–50 hp. and larger. Synchronous: One or more large motors for power-factor correction. See also transmission voltages, Table 38.

Standard a-c. voltages, together with typical applications, are given in Table 36.

Low-voltage operation causes higher operating losses and higher cost of conductor, but equipment costs less than for high-voltage. In general, the economical voltage depends upon the load factor, the power consumed, and the distance between generator and point of consumption. (See Table 38.) Distribution and interruption of current in a large mill are difficult at low voltage, and expansion is expensive; nevertheless, the usual tendency is to adopt too low rather than too high voltage.

Motors in ore dressing plants are usually 440-volt in the United States or 550-volt in other countries when only one voltage is used. Normal practice is, however, to use 2,200 to 3,300 volts for motors of 50- or 100-hp. and up and the lower voltage for the smaller motors.

Motor speed. High-speed motors are the lighter and cheaper and are usually more efficient and have higher power-factor than low-speed. Speeds recommended for general mill service are shown in Table 37.

Table 37. Motor speeds, a-c.

No. of poles	Speeds, r.p.m. 60-cycle Synchronous	60-cycle Running	50-cycle Synchronous	50-cycle Running	Max. hp. of motor advisable for these speeds: Belted	Geared
2	3,600	3,500	3,000	2,920	....	....
4	1,800	1,745	1,500	1,450	40	5
6	1,200	1,160	1,000	970	75	20
8	900	870	750	730	125	50
10	720	700	600	580	....	75
12	600	580	500	485	....	....
14	515	500	430	417	....	....

Geared motors are preferred to slow-speed motors. They have built-in helical or herringbone gears for medium and ordinary low-speed units and worm gears for units of very low speed. They are built for all speed reductions, and from small sizes to above 100-hp. Some operators prefer motors directly connected through flexible couplings with gear reducers because a motor breakdown does not throw the speed-reduction unit out of service.

Power rating. Highest efficiency and best power factor are obtained by operating a motor continuously at as near its rated capacity as possible. Hence motors for driving stamp batteries, ball, rod or pebble mills, compressors or blowers, pumps, and other steady-load apparatus should have capacities corresponding as closely as practicable to the power requirements. For driving coarse crushers, rolls, tables, agitators or settling tanks, elevators, conveyors, and other equipment subject to irregularity in feed or to excessive and variable friction a motor should have a power rating 50 to 100% in excess of the normal requirement. The bad effect of so many over-sized motors on the power factor of a whole mill is not unduly serious, because in most mills, particularly those compelled to grind fine, a large part (50 to 75%) of the total mill power is applied to steady-load equipment by efficient motors.

Table 38. Characteristics and applications of polyphase a-c. motors (*after Fick, 143 #6 J 65*)

Polyphase type	Ratings, hp.	Speed regulation	Speed control	Starting torque	Pull-out torque	Applications
General-purpose squirrel cage.	0.5 to 200 hp.	Drops about 3% for large to 5% for small sizes.	None, except multi-speed types, designed for 2 to 4 fixed speeds.	200% of full-load for 2-pole to 105% for 16-pole designs.	200% of full-load.	Constant-speed service where starting torque is not excessive. Fans, blowers, rotary compressors, centrifugal pumps, flotation machines, wood-working machines, machine tools, line shafts.
Full-voltage starting, high starting torque, low starting current, squirrel cage.	3 to 150 hp.	Drops about 3% for large to 6% for small sizes.	None, except multi-speed types, designed for 2 to 4 fixed speeds.	250% of full-load for high-speed to 200% for low-speed designs.	200% of full-load.	Constant-speed service where fairly high starting torque is required at infrequent intervals with starting current of about 400% full load. Reciprocating pumps and compressors, conveyors, primary and secondary crushers, pulverizers, agitators, groups of small equipment that can be started under small load.
Full-voltage starting, high starting torque, high slip, squirrel cage.	0.5 to 150 hp.	Drops about 7 to 12% from no load to full load.	None, except multi-speed types, designed for 2 to 4 fixed speeds.	300 to 315% of full load, depending upon speed and rotor resistance.	300%. This motor will usually not stall until loaded to its maximum torque, which occurs at standstill.	Constant-speed service and high starting torque if starting not too frequent, and for taking high peak loads with or without flywheels. Punch presses, die stamping, shears, bulldozers, bailers, hoists, cranes, elevators.
Wound-rotor or slip-ring, external-resistance starting.	0.5 to several thousand.	With rotor rings short-circuited, drops about 3% for large to 5% for small sizes.	Speed can be reduced to 50% of normal by rotor resistance. Speed varies inversely as the load. *b*	Up to 300%, depending upon external resistance in rotor circuit and how distributed.	200% when rotor slip rings are short-circuited.	Where high starting torque with low starting current or where limited speed control is required. Fans, centrifugal and plunger pumps, compressors, conveyors, hoists, cranes, ball mills, gate hoists.
Synchronous. *a*	25 to several thousand.	Constant.	None, except special motors designed for 2 fixed speeds.	40% for slow speed to 160% for medium speed 80%-pf. designs. Special high-torque designs.	Unity-pf. motors 170%; 80%-pf. motors 225%. Special designs up to 300%.	For constant-speed service, direct connection to slow-speed machines and where power-factor correction is required. Adaptable to high voltages. Compressors, blowers, centrifugal pumps, stamp batteries, tumbling mills provided with friction or magnetic clutches to apply load gradually.

a A SUPER-SYNCHRONOUS or BUILT-IN CLUTCH TYPE synchronous motor is for a load that requires high starting duty but low and constant speed, *e.g.*, ball and tube mills. One form is started as a slip-ring motor and at full speed has the characteristics of the synchronous motor.

b For heavy duty when some speed adjustment is necessary. These motors have the characteristics not of d-c. adjustable-speed motors but of d-c. motors with armature control, the current consumed in the resistance to reduce speed being wasted.

Table 39. Characteristics (*a*) and applications of d-c. motors, 1- to 300-hp. (*after Fick, 143 #6 J 65*)

Type	Starting duty	Maximum momentary running torque	Speed regulation	Speed control *b*	Applications
Shunt-wound, constant-speed.	Medium starting torque. Varies with voltage supplied to armature, and is limited by starting resistor to 125 to 200% full-load torque.	125 to 200%. Limited by commutation.	8 to 12%.	Basic speed to 200% basic speed by field control.	Drives where starting requirements are not severe. Use constant speed or adjustable speed, depending on speed required. Centrifugal pumps, fans, blowers, conveyors, elevators, wood- and metal-working machines.
Shunt-wound, adjustable-speed.			10 to 20%, increases with weak fields.	Basic speed to 600% basic speed (lower for some ratings) by field control.	
Compound-wound, constant-speed.	Heavy starting torque. Limited by starting resistor to 130 to 260% of full-load torque.	130 to 260%. Limited by commutation.	Standard compounding 25%. Depends on amount of series winding.	Basic speed to 125% basic speed by field control.	Drives requiring high starting torque and fairly constant speed. Pulsating loads. Shears, bending rolls, plunger pumps, conveyors, crushers, etc.
Series-wound, varying-speed.	Very heavy starting torque. Limited to 300 to 350% full-load torque.	300 to 350%. Limited by commutation.	Very high. Infinite no-load speed.	From zero to maximum speed, depending on control and load.	Drives where very high starting torque is required and speed can be regulated. Cranes, hoists, gates, bridges, car dumpers, etc.

a Table shows average values for standard motors.

b Minimum speed below basic speed by armature control limited by heating.

Characteristics and applications of motors in milling plants are shown in Tables 38 and 39.

At UNITED COMSTOCK, operating at 440 volts exclusively (stepped from 60,000 and 2,300 volts), the tube mills are driven by slip-ring motors with reversible controllers; more than 90 other motors in the plant (some of 200-hp.) are of squirrel-cage type, with automatic compensators and push-button starters (*114 J 846, 117 J 516*). At HONDURAS ROSARIO, mainly on 2,200-volts, 20 stamps are driven by a 200-hp. synchronous motor with belted exciter, started by a 35-hp. induction motor and automatic synchronizer; three tube mills each have a 75-hp. slip-ring motor with flexible coupling and reversing starter (no clutch); all plunger pumps have slip-ring motors; the agitator compressor has a 75-hp. squirrel-cage motor. At PANDA six synchronous motors (three of 350 and three of 525 hp., each at 6,600 volts) are used to drive 2-stage centrifugal pumps for water supply of 10,000 g.p.m. against a head of 500 ft. (*29 MM 137*). The ALASKA-JUNEAU mill contained several unusual features, made possible by an abundant supply of power from its own generators and those of the adjoining ALASKA-TREADWELL mine (*120 P 251*). Each of the two coarse-crushing sections contained one 36 × 48-in. jaw crusher and two No. 9 gyratories; these three crushers were driven by clutch pulleys on one shaft direct-connected to a 350-hp. synchronous motor of 2,200 volts and 360 r.p.m., with direct-connected exciter. The starting torque was sufficient to start all connected equipment without releasing the clutches. The slow speed of this motor obviated countershafts and other reducers, space for which was wanting. Fine crushing, in two stages, was done in 12 ball mills (8 × 6-ft.) each driven by one 225-hp. motor, and 12 tube mills (6 × 12-ft.) each with one 150-hp. motor; all of these motors were of squirrel-cage type, 2,200-volt, 435-r.p.m., specially designed for large starting torque. The mills had friction clutches, but it was seldom necessary to use them; motors were thrown directly on the full line voltage by special circuit breakers and without compensators, but extra-heavy feeder lines were installed. The unbalancing caused by these motors was compensated by the synchronous motors at the coarse crushers. Two centrifugal pumps for mill water, 3,000 g.p.m. each, were each driven by a 400-hp. direct-connected squirrel-cage motor, not specially designed for high starting torque; a synchronous torque 33% of the full-load torque proved satisfactory. These motors were excited by independent d-c. circuit. At the SANTA BARBARA mill (*112 J 1060*), with 19 motors aggregating 590 hp., three slip-ring motors of 100 hp. each are used for coarse crushing and rod-mill grinding, but all others are of the squirrel-cage type.

Conductors are of the following classes: (*a*) Exposed bare conductors for ground connections; (*b*) exposed insulated conductors mounted on insulators, for low and medium potentials; (*c*) exposed bare conductors mounted on insulators, for high potentials; (*d*) small insulated conductors in iron conduit; (*e*) large insulated conductors in fiber or tile duct.

Short-circuit currents and their effects. An installation must be constructed proof against any reasonably conceivable abnormal condition. The most important, and possibly most frequent, cause of trouble is short-circuiting, despite most elaborate precautions. Hence all measures within reasonable expense should be employed to limit the destructive effects. The initial short circuit usually results from failure of insulation. Any circuit or piece of apparatus subject to short circuits should be removed from service as soon after the short circuit has occurred as is reasonably possible.

Four important provisions against short-circuiting must always be made: (*a*) Material of fireproof or fire-resisting nature should be used whenever possible; if not possible, apparatus and conductors should be segregated and enclosed by suitable barriers or cells, so that a fire resulting from a short circuit will be confined to a small part of the installation. (*b*) All apparatus and material should have ample strength to resist the mechanical stresses resulting from the abnormal flow of current during a short circuit. (*c*) All circuit breakers that may be called upon to open a short circuit should have ample capacity to rupture the maximum current that can flow at the instant they are called upon to operate. It is necessary not only that breakers be amply insulated to operate safely at the installation potential, and that the contacts have sufficient area to carry the maximum current during normal operation, but it is also necessary to know the maximum short-circuit current that they may be required to open and to be certain that each breaker selected has ample rupturing capacity to open that circuit safely. This is one of the most important points to be considered, but unfortunately it is the one most frequently neglected, often with disastrous results. (*d*) Current should not be allowed to flow through a short circuit any longer than can be avoided.

Bare conductors are usually employed when the voltage exceeds 15,000. These consist of solid wire, copper tubing, aluminum in bars or structural shapes, or iron pipe. The use of tubing makes it possible to reduce the number of expensive insulators used for support. It is expensive and quite unnecessary to insulate such high-voltage conductors because when properly installed they are widely spaced and kept well away from the ground.

Transmission. Elementary data for rough estimates are given in Tables 40 and 41.

Table 40. Distances of transmission

Distances to which 100-kw. three-phase current can be transmitted over different sizes of wires at different potentials, assuming an energy loss of 10% and a power factor of 85%.

Number B. & S.	Area in circular mils	Voltages 2,000	3,000	4,000	5,000	6,000	8,000
		Distance of transmission in miles for various potentials at receiving end

Cable is used for interconnection of apparatus and generally for low-voltage distribution. That for interconnection should be of the best grade of material and installed in the best possible manner. The cost is but a small percentage of the total. Transmission cables may represent a considerable part of the total investment in electrical equipment when used for distribution of power to a number of isolated loads.

When large cables are multiplied to carry the current for low-voltage machines it is necessary to arrange and group the phases so that each conductor will have about the same reactance and thus the current will be properly apportioned between the different conductors in parallel. When dealing with large conductors, special care should be taken to support them rigidly so that they will not be torn from their supports should a severe short circuit occur.

Exposed cable runs. The best arrangement, provided the number of cables in close proximity does not make the group too congested or hazardous, is to use wires or cable insulated for full potential and rigidly supported on insulators good for full potential. This arrangement is safe, since each method of insulation affords full protection. Exposed runs are under constant observation. VARNISHED CAMBRIC is the most lasting insulation because it does not absorb moisture, like paper insulation, and does not deteriorate as rapidly as rubber. It should be thoroughly covered with a fireproof braid or tape to minimize communication between circuits in the event of a short circuit or ground on one circuit or conductor. A 3/32-in. asbestos tape with a flameproof braid covering gives excellent fire protection.

Cables in conduits or ducts should be stranded. Iron conduit is ordinarily used up to 4-in. diameter; above this size fiber or tile is satisfactory and less expensive. Iron should not be used with alternating current unless all conductors of the circuit are in the same conduit. Rubber-covered standard conductors with double waterproofed braid (or tape and braid) are generally used for conductors up to 600 volts and as large as 0000 B. & S. gage. Varnished-cambric insulation is by far the best for larger cables and higher voltages, provided it is covered with good weatherproofed braid for protection against abrasion. Cambric-covered cables may be run in fiber ducts, if they are carefully drained. Cables for main connections of considerable importance are frequently installed with insulation suitable for voltages 50% in excess of the rated voltage.

Lead-covered cable used on a-c. circuits should be of the multiple-conductor type. Eddy currents in the lead sheaths of single-conductor cables increase the energy losses. Single-conductor lead-covered cables should not, in general, be used for heavy a-c. circuits.

Armored cables and conduits. On d-c. circuits, where maximum copper area is desired, single conductors should be used. Single-conductor cable is preferable for low-tension d-c. mains on account of the simplicity of service connections. Concentric cables give maximum ampere capacity per duct for single-phase alternating current, but flat twin cables are usually more convenient and cheaper for mains and lines where the area is less than 250,000 circular mils. They are liable to kink and are not recommended in sizes larger than 250,000 circular mils. For two-conductor cables larger than 250,000 circular mils, either round cable (two conductors twisted together) or concentric cable is best. Triple conductor is almost a necessity in three-phase, a-c. work in order to avoid disturbance to parallel circuits and reduce loss in the lead sheath to a minimum. (If single-conductor lead-covered cables are used in a-c. circuits the sheaths should not be in contact nor connected by any low-resistance path.) Multiple-conductor cable is best for a number of small conductors run in one duct.

The cheapest cable insulation for UNDERGROUND CIRCUITS is paper, and it can be used safely when the lead cover is not subject to corrosion. The insulation on sizes smaller than No. 6 B. & S. is likely to be injured by sharp bending or handling, and for smaller conductors, rubber insulation is best. It is also best for cables placed in very wet ducts, where severe corrosion is to be expected.

Thickness of insulation is principally dependent on mechanical requirements with low-tension cables (less than 1,000-volt); for higher voltages the thickness is governed by the dielectric strength required. For 3-phase alternating current undergrounded or delta-connected, one-half the thickness of insulation should be put around each conductor and the other half surrounding the three conductors. This gives the same total thickness of insulation between conductors and between each conductor and ground. For 3-phase circuits Y-connected, with the neutral grounded, the thickness of the outer jacket may be reduced to roughly one-half the thickness of the insulation on the individual conductors, since the pressure to ground is approximately 60% of the pressure between conductors.

Finish on cables in clean, dry ducts or wooden boxes underground or in any situation where the cable is not subject to mechanical injury or liable to corrosion should be plain lead. For wet ducts, or other places where corrosion (but not mechanical injury) is to be feared, and for burying directly in clean earth, with a protecting plank or tile laid above the cable, use a jute and asphalt jacket over the lead. When mechanical injury is to be guarded against, use band-steel armor over the jute and asphalted lead. If the cable is not to be supported practically continuously, use wire-armored instead of band-steel armored cables. Such cable may be suspended for any practical distance, practically the entire strain being taken by the wire armor.

Table 42. Allowable current in copper wire and cable

0000	211,600	225	325	2,000,000	1,050	1,670

Current-carrying capacity of an insulated conductor is determined within practical limits by the maximum temperature the insulation will withstand. The temperature should not be above 85° C. for saturated paper, 75° for cambric, and 60° for rubber. The limit is lower for high voltage. The following maximum safe temperatures at the surface of the conductor in the cable are recommended in the Standardization Rules of the A. I. E. E.: For impregnated-paper insulation, $85-E$; for varnished-cambric insulation, $75-E$; for rubber compound insulation, $60-0.25E$, where E = the effective operating voltage in kilovolts between conductors.

2,000,000	3	5	6						

The maximum safe continuous load for any given cable is higher with direct than with alternating current, but the difference is of slight practical importance for conductors less than 500,000 circular mils in area. The safe load is less for 60 cycles than for 25 cycles; less in the tropics than in temperate zones; it increases markedly in winter; it decreases with the number of loaded cables adjacent to each other; *e.g.*, the average safe load in a 4-duct line would be about 60% greater than in a 16-duct line; and cables immersed in water carry at least 50% more current than those buried in earth.

Table 42 shows the carrying capacity of different sizes of cables. The figures in the table are based on concentric stranded conductors. If solid conductors are used, reduce the current given (for 30° C. rise) by 7%. For two-conductor cables, either round or flat, decrease the current given for single conductor by 15%. For two-conductor concentric cables, decrease the current given for single conductor by 25%. For four-conductor cables, reduce the current given for three-conductor cables by 12.5%. For higher-voltage cable reduce table values by 1% for each 2,000 volts that the working pressure exceeds 3,000 volts; for example, 25,000-volt cable, 11% less than the tabulated values.

Conduit sizes. See Table 43.

Current in motor terminals. See Table 44.

Table 44. Current in motor terminals

[Approximate amperes per terminal for a-c. induction motors, for determining size of wires, capacity of fuses, and setting of circuit breakers]

250	....	590	290	237	62
300	....	700	350	285	74

For single-phase motors, multiply the current for three-phase motors by 1.73. For two-phase motors, multiply the current for three-phase motors by 0.886.

Power generation. The great majority of American ore-dressing mills of medium and large size operate electrically; public-service water-generated power is normally used.

Some typical transmission lines, mostly in the western U. S., are: Alma, Colo., 250 kw., 150 mi.; Boulder Dam, 165,000 kw., 287,000 volts, 310 mi.; Golconda, Nev., 1,000 kw., 220 mi.; Inspiration, Ariz., 16,500 kw., 54 mi.; Kellogg, Id., 1,200 kw., 80 mi.; Mascot, Tenn., 1,500 kw., 120 mi.; Mill City, Nev., 250 kw., 150 mi.; Mountain City, Nev., 500 kw., 100 mi.; Silver City, Nev., 210 kw., 40 mi.; Superior, Ariz., 500 kw., 70 mi.

Hydroelectric generators are rarely warranted for an individual mill of short or unknown life owing to the heavy expense usually required for storage reservoirs, although the generating station itself may be no more expensive than a steam plant of corresponding size.

On the rugged and rainy coasts of British Columbia and southern Alaska exceptionally favorable hydraulic conditions justified erection of water-driven generators by several large mining and milling companies. Total cost of hydroelectric plants (*ante* 1917), including dams, ditches, and all equipment, was estimated at $100 to $200 per kw. capacity (*Peele*). A hydroelectric plant is equal to steam and superior to gas-engine in reliability; the most common source of delay is ice at the intake; a long transmission line is, however, always subject to interruption.

Steam generation, in plants designed for the utmost efficiency, is the practice at many large mills in the United States. Steam generation is usually preferred at small mills, where first cost is more important than fuel economy. Coal or oil is used as fuel, depending upon availability; the convenience of the latter may offset higher unit cost. The plant should be designed to furnish power at a minimum cost per hp.-hr. delivered (not rated output),

Table 45. Typical steam plants; costs of installation and operation (including "all costs")

Type—location	Installation costs			Coal, cost/ton	Cost of operation

Condensing water: temperature 75° F., for 2-in. vacuum, 55 times feed water.

including interest and amortization of plant within the life of the mill. The necessity for uninterrupted service may justify a greater outlay than would be warranted on grounds of fuel or labor economy.

The essential elements of a steam plant are boiler, engine, and feed-water pump; further equipment intended to economize fuel or labor, stated in the order in which it is usually adopted, is feed-water heater, compound engine, condenser, superheater, automatic stoker (*107 J 1121*). Fuel economy and reduced cost per unit of power generated are thus gained at the expense of simplicity (entailing more skilled supervision) and of original outlay. Turbines are cheaper and simpler than reciprocating engines, but they require more skilled supervision. The cost of typical steam-driven generating plants is given in Table 45; the approximate steam consumption of steam engines and turbines, in Table 46; and the calculated performance of various fuels and types of steam boilers in Table 47.

Table 47. Power-plant fuels; calculated performance, oil vs. coal vs. wood

[Feed water at 100° F.; steam at 100 lb. per sq. in.]

Fuels	B.t.u. per lb. fuel as fired	B.t.u. per lb. steam @ 100 lb. *a*	Pounds steam evaporated per lb. fuel, theor.	Fuel ratios, theor.	Small fire-tube, hand-fired	Medium fire-tube, Hand-fired	Medium fire-tube, Stoker-fired	Large water-tube, stoker-fired
					Boiler efficiencies			
					50%	60%	70%	80%
					Actual pounds of steam delivered per lb. of fuel			
Fuel oil	19,000	1,120.8	16.90	100.0	....	10.18	11.82	13.50
Good coal	14,000	do.	12.45	73.5	....	7.47	8.73	9.98
Medium coal	12,000	do.	10.65	63.0	....	6.40	7.45	8.50
Poor coal	10,000	do.	8.90	52.6	4.45	5.34	6.25	7.11
Lignite	7,000	do.	6.22	39.5	3.11	3.72	4.35	....
Wood, fresh cut and wet, direct-fired under steam boilers	3,000	do.	2.68	15.8	1.34	1.61	....	....
Used in gas producers	2 to 2.3 lb. wood per hp.-hr., or approx. 1/3 to 1/4 that used under boiler for same hp.							

a For other steam pressures, B.t.u. per lb. of steam are: 25 lb., 1,101; 50 lb., 1,110; 100 lb., 1,120.8; 150 lb., 1,127; 200 lb., 1,131; 300 lb., 1,137; 500 lb., 1,140; all for saturated steam, and feed water at 100° F.

A Diesel-engine plant has about the same weight and cost, per unit of installed power, as a steam-engine plant of the more elaborate types; see Table 48. It is particularly noteworthy for its high fuel efficiency up to the safe limit, which is fixed by the weight of air that can be admitted to its cylinders, but it is incapable of carrying sustained overloads. It requires skillful supervision, and repairs and renewals constitute a large item of expense,

Table 48. Costs of internal-combustion engines (1938)

[All include starting equipment]

	Hp.	Cost, $ per brake hp.
Gasoline engines (only)	25– 300	18–20 *a*

Slow-speed Diesel engines, exciter, generator and switchboard	300–2,000	75–85 *b*

1,200-hp. Deutz Diesel, 4-cycle, 6-cylinder, 720-r.p.m., complete with 150-kva. generator, exciter, and switchboard, installed in Canada, cost $11,060. Weight, 11,000 lb. (engine only).
125-hp. Deutz Diesel, 4-cycle, 750-r.p.m. engine for air compressor, installed in Canada, cost $5,500. Weight, 9,500 lb. (engine only).

a F.o.b. factory. *b* Erected.

which, however, can be diminished by regular replacement of worn valves, etc., before failure. Its best field is at plants of moderate size, where coal would be uneconomical and fuel oil expensive; its consumption averages only 30 to 40% of the amount required at a high-class oil-fired steam plant of corresponding size.

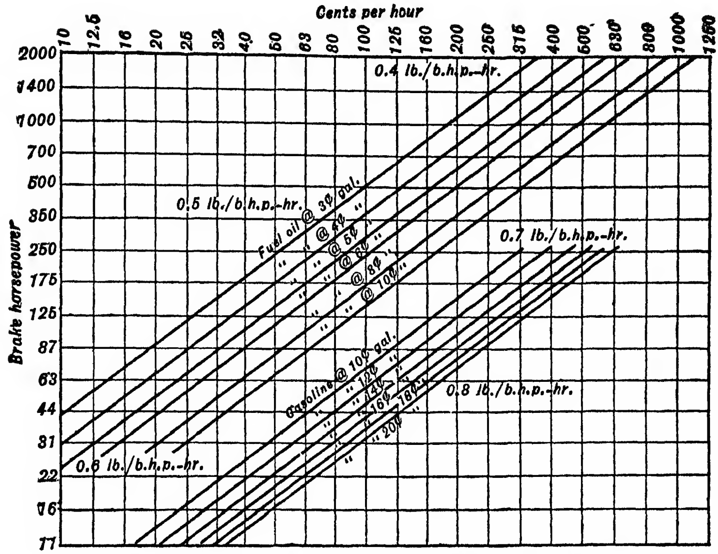

Fig. 29. Estimated costs of operating Diesel and gasoline engines.

Cost of Diesel-engine operation (also gasoline-engine) may be estimated from the diagram, Fig. 29, for various hp. and cost of fuel. They may be used down to 1/3 of the rated hp. per unit. Some examples from practice since 1925 are given in Table 49.

a Estimated.

Several gold plants (350 to 1,000 tons per day) in the Philippine Islands drive the equipment with motors from Diesel-engine generators at costs of approximately 1¢ per hp.-hr.

The following data, in addition to those in Tables 48 and 49, may be used for estimating approximate costs.

Notable installations of Diesel-driven generators were made by the Phelps Dodge Corp. at Tyrone, Morenci, Globe, and Nacozari. Those at Tyrone, at 5,950-ft. elevation (*119 P 369*), were vertical, 2-cycle, with 5 cylinders of 20.6-in. diameter and 26-in. stroke; speed, 180 r.p.m.; rated at 1,250 brake hp. at sea level. The scavenger pump was large enough to maintain a pressure of 2 to 3 lb. per sq. in. in the cylinder at the beginning of the stroke, thereby simulating sea-level conditions; this plan increased fuel consumption per available hp. but made the total cost lower by permitting investment in a smaller engine. A compressor for the oil injector, and to store compressed air for starting, was direct-connected to the engine. Each engine was direct-connected to a 60-cycle alternator of 815 to 850 kv.-a. capacity. Fuel was of the same quality as that used under steam boilers, California 14° to 20° Bé. occasionally

carrying 2% sulfur; some oil of 24° Bé. was fed just before stopping an engine, so that its first supply on starting would ignite more readily. The heavier oil was warmed by coils carrying cooling water from the exhaust jackets of the engines. Fuel consumption, per hour, varied directly with the load, from 175 lb. at 100 kw. to 420 lb. at 600 kw.; above that point, consumption increased somewhat more rapidly, being 570 lb. at 800 kw. A steam plant with the same output as the Diesel engines at Tyrone was estimated to require five times more water, 2 1/4 to 2 1/2 times more fuel, but only 1/3 as much expense for repairs and replacements. Costs for labor and miscellaneous supplies were practically identical. At Iron Mt., Mo., two 500-hp. Diesel engines drove two 436-kv.-a. generators at 2,300 volts. The cost of the whole plant (1923), including building and all accessories, erected and running, was $100,000. Operating at half capacity, with oil at $1.65 per bbl., the cost was 1.78¢ per kw.-hr. including interest and amortization (15 yr.). Betty O'Neal mill (and mine), Lewis, Nev., operated two Fairbanks-Morse 6-cylinder semi-Diesels of 300-hp., each direct-connected to a 200-kw. 460-volt alternator of 60 cycles. Fuel was 27° Bé. distillate, costing 7.1¢ per gal. at the mine; each engine consumed 17 g.p.h. The total power cost was $6 per hp.-mo. (*117 J 449*). Cooling water from the mine was chemically softened before use.

Diesel stand-by units are sometimes installed to provide against power interruption on long transmission lines; also, as at Mt. Isa, for preliminary operations, with stand-by service in mind.

Producer-gas engines are sometimes used where wood (or a poor grade of coal or peat) is plentiful and cheap, water is scarce, and other fuels are costly. The following examples of such practice are abstracted from Thomas (*Power Plants in Metal Mines*).

At Sons of Gwalia, West Australia, altitude 1,300 ft., electric current is generated at 40 cycles, 550 volts, by one 4-cylinder 500-hp., one 6-cylinder 750-hp., and one 2-cylinder 400-hp. engine, supplied by 3 producers (with one in reserve). These have 35 sq. ft. of grate area each and consume 21.4 lb. dry wood per sq. ft. per hr. Compressors supplying 2,000 cu. ft. of free air per min., at 85 lb. gage, are run by two 4-cylinder 500-hp. engines supplied by 3 producers, 20 sq. ft. of grate area each, consuming 28.8 lb. dry wood per sq. ft. per hr. Gas has a thermal value of 122 to 132 B.t.u. per cu. ft. Combined engine exhausts at 1,040° F. go to 4 boilers (1,900 sq. ft.) and 4 pre-heaters (950 sq. ft.) generating steam for hoisting; these not only save 200 to 220 tons firewood per mo. but also serve as silencers. Wood consumption is 3.7 lb. per kw.-hr. Cost per kw.-hr. (1934) was 0.67¢ for fuel, 1.36¢ total. At Lonely Reef, Bulawayo, So. Rhodesia (altitude 4,200 ft.), electric current is generated at 50 cycles, 550 volts, by four 4-cylinder 225-hp. engines. A 1,000-cu. ft. compressor is driven by a similar engine. Gas (140 B.t.u. per cu. ft.) is supplied by 4 updraft suction producers (1 in reserve), with wet scrubbers, tar extractors, and 2 dry scrubbers (scrubber water 50 g.p.m. per producer). Wood consumption is 3.4 lb. per kw.-hr. Cost per kw.-hr.: fuel, 0.42¢; total, 0.80¢. At New Goldfields, Venezuela (altitude 570 ft.), electric current is generated at 50 cycles, 3,300 volts, by two 6-cylinder 400-hp. engines (with 1 stand-by and 1 under repair), supplied with gas by eight 300-hp. updraft producers, each with wet scrubber, tar extractor, and 2 parallel dry scrubbers. Gas temperature, 86° F. Cooling-water consumption, 452 g.p.m. Wood consumption, 3.98 lb. per kw.-hr. Cost per kw.-hr.: fuel, 0.67¢; total, 1.36¢. At Globe Phoenix, So. Rhodesia (altitude, 4,050 ft.), electric current is generated at 60 cycles, 550 volts, by three 6-cylinder 375-hp. engines, and power for a compressor for 1,710 cu. ft. of free air per min. at 100 lb. gage is supplied by two 3-cylinder 185-hp. engines, all served by 7 Crossley Type G bituminous-coal producers with scrubbers and tar extractors. Consumption of 13,000-B.t.u. coal is 1.8 lb. per kw.-hr.; cost per kw.-hr.: fuel, 0.50¢; total, 0.89¢.

8. LIGHTING

Window lighting can serve the usual mill 6 to 10 hr. per day. Modern mills have windows spaced closely along the walls, with full lines at the roof breaks; they should be high enough to pass light well into the mill. Glass areas sometimes run as high as 40% of the floor surface. On the other hand, window areas dissipate much heat, and, since 1 watt of Mazda lighting is equivalent to 1 sq. ft. of glass, the economical balance in cold northern climates with short winter days may well tilt in favor of artificial lighting in daytime. The balance may tilt similarly where air conditioning against summer heat calls for insulated walls in the usual window spaces. Even in mills with ample window space, artificial light is necessary in many parts of the building during the daylight hours for operating safety and for efficient inspection. The amount of light that should be supplied is that which simulates indoor daylight of suitable intensity. With Mazda lamps, 1 watt per sq. ft. of floor area is the minimum recommended for discriminating details; for general illumination half this value will be sufficient.

Methods of illumination (*123 P 751, 61 EW 628, 70 EW 6, 201; 72 ER 907, 9 Trans. Illum. Eng. Soc., 814*). In a small mill, 50-watt lamps or larger, with reflectors and waterproof sockets, are suspended by cords, wherever needed; they should be within reach for easy cleaning and replacement, and the number should not be stinted. With power at 1¢ per kw.-hr., the total cost for lighting with Mazda lamps (including replacements) is 3¢ to 4¢ per 1,000 candle-power-hours. One c-p. = 0.75 watt in this type of lamp. Globes and reflectors should be kept clean. Drop lamps are necessary for close work, but produce

glare, which reduces acuity of sight and tires the whole body; breakage of lamps is liable to be excessive and the cost of wiring is high. General illumination with a relatively small number of large, efficient lamps is now in extensive use for all types of industrial lighting and is well suited to large ore-dressing plants. When the arrangement of a mill is such that the greater part of the area needs only relatively low general illumination while a few operations require much higher intensity, the most economical plan is to use overhead lights with proper reflectors for uniform minimum intensity, and supplement these with local lamps placed wherever close inspection of machines or products is necessary. It is probably an economy to install nearly double the number of sockets that will be needed in normal use, to provide for emergency lighting and to have spares currently available in place. Theftproof lock sockets will prevent too great loss. In some of the most modern plants, portable lamps are issued in the same way as special tools, and conveniently located wall outlets are installed for attaching them; continuous use of such lamps should, however, be discouraged by providing sufficient regular lights to furnish illumination of machines from more than one direction. Yards, particularly around doors and at special working spaces, should be flood-lighted.

Lighting circuits may be either a low-voltage (110-volt) system on a separate transformer or individual dynamo or a high-voltage series type or multiple system. The series circuit is more efficient, lower in first cost, and easier to maintain than multiple systems. The layout is the same as for multiple

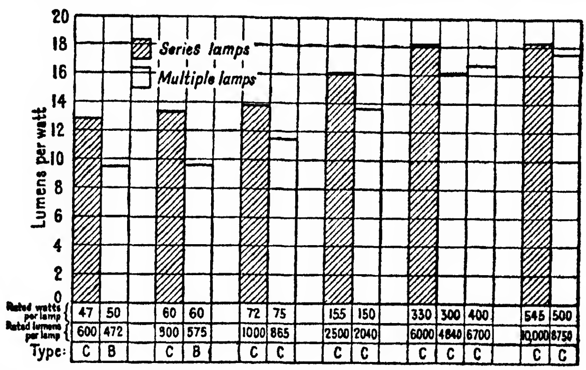

Fig. 30. Relative efficiencies of multiple and series Edison Mazda lamps.

circuits, except that series sockets, lamps, and reflectors such as are used for street illumination are necessary. Lead-covered, single-conductor cable. No. 8-gage, is most economical, since it can be run on girders, etc., without insulators or pipe conduits. For comparative efficiencies of the two systems, see Fig. 30. Series circuits are fully safeguarded from the effect of high voltage coming from an open-circuited secondary, lamp burnout, etc., by suitable protective devices. Lamp operation is protected by a film cutout in each socket. In case a lamp burns out, the film cutout is punctured in the socket, which permits current to flow through the circuit without interrupting the operation of other lamps.

The series circuit may be found advantageous for the large units; but since portable tools are unsuitable for use on series circuits, and since they are most used near the zones of maximum light intensity and are most easily energized from the lighting circuit, it may be found advantageous to use the multiple system for such areas. The two circuits resulting would insure some light in case of failure of either from internal causes.

Lamps. The inside-frosted Mazda C lamp is most useful for general illumination; it is efficient and sturdy; the smooth white mineral coating on the lower portion of the bulb diffuses the light, eliminates glare, and makes the shadows soft and feathery rather than dense and harsh. Lamps larger than 300-watt have Mogul bases, requiring large sockets; Daylight glass is probably best for these. Standard voltage is 115; 220-volt lamps are obtainable but are not so sturdy.

Metal-vapor lamps are being increasingly used (1938) in mines, mills, and industrial plants generally. Mercury and sodium are the usual metals employed.

Mercury lamp, when used in combination with approximately 25 to 50% Mazda lighting, works out very satisfactorily for general milling areas and for crushing plants, motor-generator rooms, underground machine shops, pipe tunnels, and places where a high degree of lighting is necessary for maintenance of equipment or for safety, and for flotation rooms, sorting plants, and electrolytic zinc and copper refineries, where a high degree of color differentiation must be accomplished. These lamps come only in

large sizes, approximating 10,000 lumens; each such lamp should be supplemented with approximately 100 to 200 watts of Mazda light in order to avoid stroboscopic effects.

Table 50. Power consumption of lamps

Type	Watts	Lumens	Volts
Mazda	100	1,530	115
	200	3,400	115
	300 *a*	5,900	115
	500 *a*	10,000	115

	200	2,210	....
	300 *a*	3,590	....
	500 *a*	6,370	....
Mercury-vapor	250	7,500	....
	400	16,000	....
Sodium-vapor	225 mult. series	10,000	110/120
	195	10,000	31.4

a Mogul base.

Sodium-vapor lamp, similar to the mercury lamp except that the light is yellow in color, has a high penetrating factor. It is particularly useful in zinc-casting plants and other smelters, especially around reverberatory furnaces and converters. The light intensities used may be as low as 5 to 8 foot-candles; if the intensity is increased to approximately 10 foot-candles, daylight visibility is effected.

The cost of operation of both sodium and mercury lamps is approximately 1/3 that of standard Mazda lamps for the same degree of illumination; the life of both is much longer, provided they are burned nearly continuously, *i.e.*, not turned off and on frequently; they cannot be used where voltage variation exceeds 2 1/2%.

The sodium lamp is especially good for lighting open-pit operations, haulageways and trackways, yards and other outdoor places, owing to high penetrating factor and low operating cost. The first cost of a 10,000-lumen mercury-vapor or sodium-vapor lamp is approximately $50.

Power consumption of lamps of different types is given in Table 50.

Mercury tubes have proved satisfactory at MIAMI and other large mills. Sodium lamps have been used extensively at Hudson Bay. Iron arcs are used at the Franklin plant of the New Jersey Zinc Co. to show apple-green willemite on the tables; also by the Nevada-Mass. Co. for recognition of scheelite, in the same manner.

Reflectors. Dome reflectors are ordinarily used for general or localized-general illumination. Deep-bowl reflectors tend to reduce the light on vertical surfaces; they are especially serviceable for low-hung lamps. Angle reflectors are used where high illumination is required on vertical surfaces and where lighting units must be located on the side walls. Additional means of diffusing the light are sometimes used, *e.g.*, a polished metal cap placed over the lower half of the lamp bulb, or opal-glass caps or a metal shield on a level with the filament. These devices tend to eliminate sharp shadows. Prismatic-mirrored and dense-opal deep-bowl reflectors are also used. Enclosed or semi-enclosed units of opalescent or diffusing glass produce excellent diffusion with but slight sacrifice of efficiency.

Lamp spacing. The standard dome reflector and bowl-enameled Mazda C lamp has become almost standard equipment for mill lighting. Assuming that this unit gives out a certain definite amount of light, the advisable spacings of different sizes are as shown in Table 51.

Table 51. Spacing of lights

9. HEATING

Heating of mills in cold climates is necessary not only for comfort but to avoid delays due to freezing. Practically every important mill in the United States and Canada, except a few in the Southwest, makes special provision for heating during the winter; in small mills stoves are sufficient, but

general practice is to install radiators, steam, water or electrically heated, with or without auxiliary air circulation.

The walls, roof, and floor of a mill building give up heat to their surroundings at rates proportional to the temperature gradients and to the conductivities of the respective enclosing materials, as shown in Table 52. For windows, calculate as though unbroken wall, then add the glass loss at the difference in coefficient for wall and glass.

Table 52. Heat losses through building enclosures

Walls and roof: corrugated iron, unlined, tight	1.5
Walls and roof: corrugated iron, loose	2.0

a B.t.u. per sq. ft. per hr. per degree F. temperature difference.

In addition to the above, the following infiltration losses should be added for 5 mi. per hr. wind velocity, and 60° F. temperature difference: Fixed wood sash, 23 B.t.u. per hr.; double wood sash, 45 B.t.u. per hr.; double doors or steel sash, 9 B.t.u. per hr.; outside doors or steel sash, 18 B.t.u. per hr.

To estimate K for more than one wall or heat-conducting body, apply the following formula, where K_1, K_2, etc., are the above or similar tabular values:

$$K = \frac{1}{\frac{1}{K_1} + \frac{1}{K_2} \cdots + \frac{1}{K_n}}$$

Steam-heating. An average radiator surface of 1 sq. ft. (with steam at 5-lb. pressure) suffices for 150 to 200 cu. ft. of mill depending on the severity of the climate. Based on the area of radiators alone, the boiler rating should be 1 hp. per 50 sq. ft.; including the radiating surface of supply- and return-steam lines, 1 boiler hp. per 80 sq. ft. of total radiating surface is usually ample. Radiators should be trapped and condensate sent back to the boiler, either directly or by way of a sump and pump.

Radiator shown in Fig. 31 uses only stock materials (headers are cast iron), is easily and quickly constructed, and has ample allowance for unequal expansion; the latter provision could also be made, with parallel headers, by a right-angled bend, setting the radiator in a corner. For stated lengths A, the amounts of 1-in. pipe and the total radiating areas are as given in Table 53.

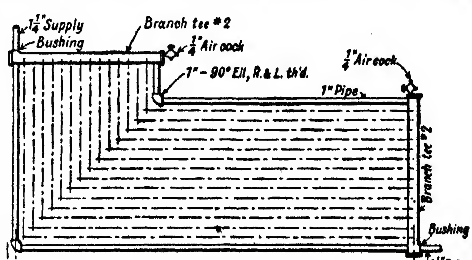

FIG. 31. Outline sketch of mill radiator.

A continuous horizontal-pipe radiator, with U-joints, requires no left-hand threading, and is cheap and easy to construct, but where a large heating effect is required this design is objectionable because condensed water may overload the lower runs and retard steam circulation. A pipe grid providing parallel flow between parallel headers requires right- and left-hand threading, is difficult to make up tight, and is likely to develop leaks on account of unequal expansion. Welded grids require skillful welders.

Table 53. Data for radiator shown in Fig. 31

A, feet	1-in. pipe, linear feet	Radiation, square feet	Cost (1924), complete
10	168	56	$63.25
12	200	67	67.05
14	232	78	70.85
16	264	89	74.65
18	296	100	78.45

Radiator fittings	Connecting fittings
2 Crane c.-i. branch tees No. 2, with 16 @ 1-in. branches, 1/4-in. tap at inlet end, 1 1/2-in. tap at outlet. 2 Bushings, 1 1/2- to 1 1/4-in. 2 Air cocks, 1/4-in. 16 @ 1-in. 90° ells, right- and left-hand threaded. 8 Hook plates for 1-in. pipe, 4 hooks each, spaced 2 1/2-in.	2 Kewanee unions, 1 1/4-in. 2 Gate valves, 1 1/4-in. 3 Standard 90° ells, 1 1/4-in. 2 Street 90° ells, 1 1/4-in. (The above fittings allow for a swing joint in the supply line, and one ell in the return line.)

Hot-water heating permits a relatively low temperature heating medium. The ordinary mill building is well suited for gravity hot-water heating, the boiler being placed at the bottom of the mill. Such a system will circulate by gravity against a friction head of 0.1 to 0.2 ft.; a circulating pump increases this head to 10 or 20 ft., and increases the velocity 10 times, making the system as responsive as steam and permitting the use of smaller pipes.

Radiation from radiators or uncovered piping without air blast is about 3 B.t.u. per sq. ft. per hr. per deg. F. temperature difference.

Unit heaters have been almost universally adopted within the past 10 yr. for heating large areas, such as mill buildings. They comprise a fin radiator heated by steam or hot water over which air is driven by a disk fan, or, in the cabinet types, by a centrifugal fan. Deflectors throw the air toward the floors, or horizontally as far as 100 ft. Motors are usually single-phase, 1,800-, 1,200-, 900-, or 600-r.p.m., either 1-, 2- or 3-speed. Heat delivery is substantially proportional to fan speed. Table 54 gives data on selected sizes. Factory cost is $1.50 to $1.00 per 1,000 B.t.u. except for the smaller sizes, which cost somewhat more.

Table 54. Unit-heater data

Width × height, in.	Lb. condensed per hr. (2-lb. steam)	Air entering @ 60° F.			Motor hp.
		Cu. ft. per min.	Temp. leaving, deg. F.	B.t.u. per hr.	
Disk-fan type					
12 × 14	32	500	120	30,000	1/30
15 × 18	65	1,000	120	63,000	1/10
18 × 21	115	2,000	100	110,000	1/6
23 × 26	155	2,300	120	150,000	1/6
29 × 33	310	5,000	115	300,000	1/2
Cabinet-blower type					
74 × 60	500	8,000	116	500,000	2
92 × 72	800	13,000	116	800,000	3
108 × 84	1,100	18,000	116	1,100,000	3

For hot water or higher-pressure steam, multiply B.t.u. and condensation by the following factors, which are about proportional to temperature differences:

	Temp. °F.	Multiplier
Hot water	180	0.75
2-lb. steam	217	1.00
20-lb. steam	260	1.20
100-lb. steam	338	1.60

Thermostatic control is advantageously applied to unit heaters. The heating rate with the motor stopped is approximately 15 to 25% of that with the motor up to speed, so that all control can be on the electrical circuit and is correspondingly inexpensive.

Stoves may be used as unit heaters in small mills by supplying an electric fan with deflectors to throw the heat downward along the floors toward the active areas, or a hot-air furnace with a fan in the duct system may be used; when equipped with a stoker it can use slack coal and requires little attention.

Electric heating. Unit electric radiation-type heaters are practical where power costs are low. A late form of this has been installed at the South Main shaft of the HUDSON BAY MINING & SMELTING CO. The heaters consist of a totally enclosed resistance unit operating at approximately red heat. Heat transfer is produced by air from a large fan. The heaters can be made in any size from 10 kw. up to 500 kw. Installation and operating costs are the lowest now obtainable with electric energy. Such heaters utilize 600 volts or less, 3-phase, and cost about $20 per kw. installed. (1 kw.-hr. = 3,413 B.t.u. per hr. radiation.)

Electric steam generators have been used for heating and other process steam in localities where electric power is relatively cheap or fuel is abnormally costly. These generators are of resistance or direct-immersion type. The resistance type is used for small installations, 20 to 75 boiler-hp.; initial cost is approximately $40 per boiler-hp., not including installation. The immersion type is used for duties of 300 to 10,000 boiler-hp.; the cost ranges from about $15 per boiler-hp. for the smaller sizes to less than $5 for the large. These units produce steam for 0.2¢ per kw.-hr. with coal @ $12.50 per ton. Either type can be made fully automatic. HUDSON BAY MINING & SMELTING CO. uses the direct-immersion type for general heating, using 150-lb. steam.

Cost of heating the average mill building with extreme temperatures of 25 to 35° below zero F. will be about 5¢ per ton of ore, charged against the year's tonnage. If buildings are brick, with other equally good insulating features, the cost is reduced about 50%. On the assumption that the period of time during which heating is required is proportional to the extreme temperature drop below 60° F., the following cost of heating may be applied: if to −30° F., 5¢ per ton; if −21°, 4¢; −9°, 3¢: if to +4° F., 2¢; +20°, 1¢ per ton.

10. FIRE PROTECTION

Fire protection in a wood-frame mill should include as many of the following precautions as necessary: (*a*) Portable extinguishers, desirable in all mills. (*b*) Automatic water sprinklers, advisable in all wooden mills of large extent. If sprinkler lines are liable to freeze, the dry system of control must be installed. (*c*) Fire mains under constant pressure and used for no other purpose, with hydrant valves at frequent and convenient intervals, to which hoses and nozzles or monitor nozzles are permanently connected; this system is considered adequate for small mills, and may render the installation of a sprinkler system unnecessary. (*d*) Well-organized and regularly trained force of fire fighters, without whom the most elaborate system of equipment would be of little value in an emergency. (*e*) Cleanliness in all respects, but particularly in the use of oils and similar materials, with special precautions against accumulations of inflammable debris.

General. Because of wide variation in fire protection requirements, caused by differences in geographical and plant conditions, each case should be studied carefully by competent authorities. In general, fire insurance rates have a more or less uniform base, with credits for favorable factors and penalties for unfavorable conditions. Advice on the problem generally, as well as detailed specifications for the most suitable installation in a given mill, may be obtained gratis from: government boards of fire underwriters; local insurance inspectors; reputable fire insurance companies, all of whom maintain engineers for this express purpose.

Portable extinguishers are particularly useful because of ready availability to the operating crew at all times. In an inflammable mill, the points requiring most protection are: vicinity of oil feeders and storage, boiler rooms, store rooms, electrical switchboards, change rooms, and the neighborhood of equipment requiring copious lubrication.

Soda-acid, 2 1/2-gal. extinguisher is satisfactory for small fires in wood, rubbish, etc., not impregnated with oils or grease, but should not be used against fire in proximity to high-tension electric circuits; it must be protected against freezing. It is made also in 20- and 40-gal. sizes mounted on wheels.

Anti-freezing, 2 1/2-gal. tank, contains calcium chloride solution, which is discharged by pressure generated by an automatically ignited cartridge; this has the same limitations as the soda-acid type, but does not require protection against cold.

Foamite extinguishers in 2 1/2-gal. hand tanks and 40-gal. wheel-mounted tanks, contain solutions of aluminum sulfate, sodium bicarbonate, and a froth stabilizer (licorice extract). On mixing these solutions by inverting the tank, a frothy stream is discharged. The smothering effect is due to a blanket of CO_2 held in a mass of bubbles made tough by aluminum hydroxide. It is suitable for ordinary fires, and particularly for those involving oils and grease, but is not safe for fires near high-voltage electric circuits, although the stream of foam, after the momentary discharge of ungasified solution, is a poor conductor. Foamite does not injure electric insulation; tanks must be protected from freezing.

Carbon tetrachloride is the only fire-extinguishing medium that can be used with safety around high-tension electric circuits. For other fires, including those in oil or grease, it is also serviceable, but

the small size of the containers adopted by manufacturers (usually 1 or 1 1/2 qt.) limits its effectiveness on a fire that has gained much headway, while the necessity for pumping the container is also a drawback to its efficiency. The tetrachloride supplied by extinguisher manufacturers contains ingredients to reduce its freezing point, and no protection against cold has to be given; no other than the special tetrachloride should be used. In the vicinity of electrical equipment or oil supplies, a unit of two tetrachloride extinguishers should be provided for 2,500 sq. ft. of floor, and within 15 ft. of any specially hazardous point.

Automatic sprinklers, held closed by fusible links, are recognized by insurance companies as the most efficient form of protection against incipient fires. If sprinklers are installed, the standpipe and hose equipment may safely be reduced. The following recommendations apply particularly to the type of construction commonly found in wood-framed mills (*after Regulations of the National Board of Fire Underwriters governing the installation of automatic and open sprinkler equipment, New York, 1922*):

(*a*) The entire mill should be equipped with sprinklers, not merely that portion where fire is most likely to begin; any unsprinklered areas must be cut off by fireproof walls. (*b*) Sprinklers must be in upright position (deflector on top), must have 24 in. of wholly clear space below them, and should be 6 to 8 in. below the ceiling or the bottom of joists. (*c*) One sprinkler must be provided for 80 sq. ft. of area, spaced, say, 8 ft. on lines 10 ft. apart, the sprinklers being in staggered rows. No sprinklers should come within 12 in. of a post, hanger, or other vertical obstruction, nor within 2 ft. of wall or partition. (*d*) Under a pitched roof, one line of sprinklers should be installed under the peak, or two lines each not more than 2 1/2 ft. from the peak. (*e*) Preferably, no branch line should carry more than eight sprinklers. (*f*) Reducers, not bushings, should be used for connecting pipes of different size; couplings should not be used unless practically unavoidable. (*g*) DRY-PIPE SYSTEM should be adopted only in those parts of a mill where water pipes would be liable to freeze; the air capacity of a dry-pipe system controlled by a single valve should not exceed 115,500 cu. in. (*h*) The air pressure in a dry system (maintained by compressor) should not be more than 15 to 20 lb. in excess of the normal tripping pressure of the automatic water valve; the dry system should not leak more than 10 lb. pressure per week. (For detailed specifications, see the cited publication, obtainable on request.)

Water mains exclusively for fire-fighting purposes should be connected with tanks of ample size (50,000-gal. minimum) maintained constantly at full capacity; this is conveniently arranged by setting the fire tank first in series with the mill-water tanks and allowing it to overflow into them. Usual Canadian practice is to install elevated dual-purpose tanks, providing both fire and domestic supply, the reserve for fire fighting being maintained by drawing the "domestic" supply from a point high up in the tank.

Fire mains should also be connected with other sources of water supply available either instantly or by starting special fire pumps. If connection for this purpose must be made between the mill system and the usual separate domestic supply of the community, precautions must be taken to avoid contamination of the latter by installing a tight check valve which will not yield until the pressure on the mill side is considerably below that on the domestic side (this valve must not be forgotten during any readjustments which may affect the pressure on either side); a safer method is to discharge the domestic water into the fire tank from an open pipe. Ground reservoirs are sometimes piped in for emergency supply. Their use accentuates the necessity, always present, to take precautions to prevent sedimentation from raw water in tanks and mains. Freezing must also be guarded against. In cold countries this involves burying or boxing in the mains.

Pressure must be sufficient to reach the highest point of the highest structure on the property. A minimum pressure of 75 lb. per sq. in. should be provided for the highest fire hose connection. Mains and principal hydrants should be strategically located at least 50 ft. outside the buildings; near the most hazardous points inside, other connections should be provided for lines of 1 1/4- or 1 1/2-in. hose, which is as large as one man can handle at adequate protective pressures. Hose permanently connected to outside hydrants, not over 100 ft. in length (but with other 50-ft. lengths at hand), should be of standard 2- or 2 1/2-in. size without rubber. The standard NOZZLE for this hose has 1 1/8-in. orifice (passing 250 g.p.m. at 45-lb. nozzle pressure), but with the higher pressures available at a well-protected mill, orifices of 3/4 and 1 in. are sufficient. For the smaller hose, the nozzle opening should be 1/2 in.

Fire-fighting forces are of little use unless well organized and thoroughly trained by frequent practice. Organization should be effected in the early stages of the development under the charge of a suitable foreman. Every member should be instructed in the manner of reporting a fire, use of portable extinguishers, the location of hydrants, the fire-piping system and the interrelation of its valves, the water resources at immediate command and methods of adding to them, and the use of smoke masks. All of this information can be best communicated by printed instructions, supplemented by regular practice and "surprise" drills with teams so organized that a sufficient number of trained men will be on duty every shift. Suggestions for organization and training are published by the National Board of Fire Underwriters. Training in FIRST AID should also be provided in connection with fire training.

Cleanliness, always desirable on general principles, is particularly necessary in those parts of an inflammable mill subject to spill of lubricating and flotation oils. Journals that require frequent oiling should have drip pans or similar devices. Feeders for flotation oils should be similarly equipped. In a small mill, where flotation oils are transferred directly from barrels to the feeders, the area of floor used for this purpose should be made fireproof, if possible; otherwise it should be covered with sheet iron with raised edges, and sand spread on the floor, to be shoveled out and replaced as often as necessary.

Miscellaneous protection. Woodwork in the vicinity of electrical machines, switchboards, and other equipment subject to sparking should be protected by covering of galvanised iron, asbestos board, or other fire-resistant material. Fire doors are advantageous in conveyor galleries and similar locations. Mine plants should be protected from forest fires by clearings of adequate area surrounding the entire group of buildings. Adequate lighting is an important factor in reducing fire hazard.

Fire insurance rates on mill buildings start from the following bases per $100 of insurance per year:

Wet-process mill, $1.25; frame building, $0.75; wet-process mill with complete sprinkler system, $0.45 to $0.65. To the above base rates increases or decreases are applied as stated in Table 55.

Table 55. Changes in insurance base-rates on frame mills, cents per $100

	Increase	Decrease
Foundation and floors:		
Concrete foundation	..	10
Concrete floors	..	10
Wood posts	10	..
Floors other than earth, concrete or stone	10	..
Sides of building:		
Metal on steel skeleton	..	20
Hollow tile	..	50
Composition or asbestos sheets	..	5
Combustible lining	10	..
Not limewashed each year	10	..
Roofs:		
Wood shingles	25	..
Metal-clad, asbestos, or composition shingles	..	10
Height, each story over 2 (maximum 25¢)	5	..
Area over 5,000 sq. ft., per 1,000 sq. ft. (maximum 25¢)	2	..
Heating, stoves, first	5–10	..
Stoves, additional, each	3–5	..
Boilers, mill building or attached	40–60	..
Chimneys, steel through roof	10–20	..
Brick, low for coal; high for wood fuel	0	0
Lighting, nonstandard wiring	5–25	..
Coal oil	25	..
Motors, recommended installations	2	..
Nonstandard installations	10–25	..
Engines, gasoline or oil	15	..
Transformers in mill	25	..
Roasting or drying furnace	10–50	..
Shops and building within 30 to 50 ft.	5–7	..
Protection:		
Underwriters pump 250 g. p. m.	..	20–25
Each added 250 g. p. m. capacity	..	10
Private pumps, 1-in. stream, all parts	..	5
Private pumps, 2 @ 1-in. streams, all parts	..	10
Standpipe and hose	..	10
Watchman and clock	..	10
Casks and buckets, or extinguishers, underwriters list	..	10
Other hazards: oils, oily waste, explosives, chemicals, steam pipes, bearings, exposure to other buildings, bushes, and yard	..	Special

Recommendations: Complete sprinkler system; transformer house, all concrete; concrete floors and foundations; central heating plant; shops separate over 50 ft. away; no gasoline auxiliaries; 2 1/2-gal. fire extinguishers as directed, about 1 per 10 to 20 tons of daily capacity (or equivalent casks or tanks with buckets); hand-controlled sprinklers in crushing department.

Use and occupancy or business interruption insurance costs about 75% of fire insurance and pays for net loss of profits and such fixed charges and expenses as must continue during the period of reconstruction after a fire.

11. DUST COLLECTION

Dust is likely to be produced in troublesome amounts in any dry-crushing and screening plant treating material carrying less than 7% moisture. If allowed to migrate freely, it may seriously endanger the health of operators, particularly if it is siliceous; it will increase wear on machinery, particularly electric motors, and will cause operating delays due to

slipping belts; it may cause loss of valuable ore amounting to from 0.1 to 1% on the crude, depending to some extent on climatic conditions. In base-metal plants the dust assay may be double that of mill feed; in free-gold plants, particularly in moist climates, dust assays are usually lower than mill heads. Motors can be protected somewhat by grouping them in an isolated room and driving the mill by line shaft, or by interposing an extra long shaft between a piece of equipment and its direct-connected motor, which can then be situated in an adjoining and dustproof room, but the most satisfactory method of control is to confine and collect the dust at its sources.

Collection may be effected by means of hoods over the offending machines, but hoods, if large, are likely to interfere with operation. It is better to so arrange suction from the dust zone of an offending machine that there is an in-draft of air toward the machine from all sides. Some plants combine overhead hoods and side or bottom suction.

Screens should be completely housed; exit openings from belt-conveyor galleries should be narrowed down with close-fitting partitions and doors, and a weighted canvas or rawhide brattice cloth should be hung over and close to the carrying belt; elevator and conveyor head pulleys should be housed and connected to the suction system. Where a fine-ore bin discharges, as, for instance, onto a belt conveyor, or where one conveyor discharges onto another, the dust may be collected by a hood; or an air-atomizing water spray may be effective.

Where collectors have been installed the value of the dust has often been more than enough to defray the whole expense of its collection.

Design of suction system. (See also Sec. 9.) The volume of air required to be moved into the system depends on the kind and number of machines served; allowances of 2,000 to 2,500 cu. ft. of free air per min. for each large primary or secondary crusher or screen handling an equivalent tonnage of dusty material, and 400 to 500 cu. ft. per min. for each conveyor-junction housing, should be ample. An air velocity of 3,000 ft. per min. is sufficient to transport any ordinary dust; higher velocities cause unnecessary abrasion. Piping should be so designed as to maintain substantially equal velocities in headers and branches, without recourse to valves and dampers except for shutoff on branches. Connections between hoods and suction pipes should be by bolted flanges, to permit quick dismantling; other joints in the suction line should be riveted and soldered, with laps in such direction as to cause minimum friction. For straight pipe, 16- or 20-gage galvanized steel is best; on curves, 16-gage. Radius of bends (measured from the center line) should not be less than 1 $^1/_2$ times the diameter of the pipe, but there is no advantage in a radius greater than twice the diameter. Unless the headers are equipped with hopper pockets and gates at short intervals, they, as well as all other pipes, should have an inclination of 30° or more (preferably 45°) from horizontal to allow dust to be withdrawn on stopping operations.

Precipitation method (see also Sec. 9) depends on completeness of recovery required. The apparatus used includes cyclones, baffle separators, filters of various forms, spray chambers, and electrostatic precipitators. CYCLONES catch only 70 to 80%, comprising the coarser portion; cotton- or woolen-bag FILTERS following a cyclone make an efficient arrangement. ELECTROSTATIC PRECIPITATORS (Cottrell) are much used in cement plants because their recovery is high and the recovered product is dry and easily returned and mixed with the plant product; but the large outlay for such a plant seldom justifies its adoption for a wet concentrator. An ordinary circular SPRAY CHAMBER is less efficient than the devices discussed above because the fine dust is very resistant to wetting and escapes, but if the dust-carrying gas is forced to ascend through packed or plate towers countercurrent to water, dust precipitation is greatly increased. In such designs adopted by power companies operating in congested areas, dust recovery of 99% and better has been realized.

In the TAUBER PROCESS the gases are caused to bubble through a shallow layer of water containing an oily frothing agent; a froth or foam is formed in which the finest dust particles are intercepted.

At a dry-crushing mill at KALGOORLIE (*114 J 1070*) one 36-in. Sturtevant suction fan, at 1,000 r.p.m., drawing 5,000 cu. ft. of air per min., collected dust from six large crushers. Branch pipes were 9 in. diameter; main header, 18 in., equipped with V-traps and vertical risers for collection of the coarser particles. The dust assayed higher than the original ore. It was caught in a cyclone collector followed by a chamber having double walls of fine burlap, with rapping devices, and hoppered bottom with screw conveyor. The original installation at ARIZONA COPPER Co., in 1917 (*22 CME 207*), when crushing 250 tons per hr. to $^3/_4$ in., with ore averaging 3.85% moisture, required seven hoods to cover one gyratory and grizzly, two horizontal disk crushers, and two pairs of rolls. The suction pipes were 8 in. diameter, except that from the gyratory hood, which was 10 in. The wet collector was a cylindrical tank of $^3/_{16}$-in. steel, 10.5 ft. diameter by 15.5 ft. tall, with tangential inlet near the top. The exhaust, through the top, came from inside a cylindrical shroud, 7 ft. diameter, extending down to within 6 ft. of the bottom of the tank. Water sprays impinged against this shroud, inside and out, and muddy water collected in a concrete basin on which the tank rested, flowing out through a water-sealed trap to flotation. The suction fan, following the wet collector, was a Sturtevant No. 70, exhausting 11,100 cu. ft. per min. at

577 r.p.m., and 3.5-oz. negative pressure; motor input, 23 hp. The dust collected was 0.0367% of the weight of ore crushed, assayed 2.34% Cu, and consumed 6,552 gal. of water per ton, which was probably more than actually necessary. A later installation by PHELPS DODGE Co. (*117 J 165*) had two similar units each comprising a motor-driven Sturtevant fan No. 80, dry collector, and wet collector. On fairly dry freshly mined ore, the system collected 8 to 10 tons of dust per shift (80% from the dry collector), of which 1% was coarser than 65-m. and 93% finer than 200-m.; its assay was about double that of the original ore. Each wet collector used 10 gal. of water per min. When working on oxidized ore from the stock pile, about twice as much dust, of the same fineness, was collected, and its assay was the same as that of the ore. At NACOZARI, a similar but smaller installation collected 3 tons of dust per shift, produced entirely by coarse crushing, assaying twice as much copper as the original ore. At a rock-crushing plant at CORONA, CALIF. (*116 J 889*), trommels were enclosed in jackets connected by suction pipes to two Sly type-A units, each having 3,000 sq. ft. of filter cloth and passing 10,000 cu. ft. of air per min. They collected 1.5 tons of dust per hr., coarse particles having been settled previously in a baffled chamber. Suction was stopped for 10 min. every 4 hr. to rap the filters. At UNITED VERDE crushing plant (*117 J 396*), dust was withdrawn from groups of four jaw crushers, four vibrating screens, four disk crushers, and four rolls by a separate duct from each group. The ducts had cleaning pockets and gates every 15 ft. Fine dust was caught by plate-and-wire Cottrell precipitators, collected in hoppers, and discharged into cars delivering to roasters. A negative pressure of 6-in. water-gage was produced by two 45,000-cu. ft. fans, each direct-connected to a 125-hp. motor. At AJO leaching plant (*114 J 184*), crushers stand above a tunnel containing a belt conveyor on which the crushers discharge; when operating, the ends of the tunnel are closed by doors, and air is exhausted by a suction fan delivering to a group of cyclone separators.

At MCINTYRE PORCUPINE, crushing 2,400 tons per 16 hr. from 7 to $^3/_{16}$ in., moisture was 1.5–2.5%; air volume under and over one 7-ft. cone was 2,000 cu. ft. per min.; from one 78×18-in. rolls, 2,000; from surge bin and screens, 2,500; from two conveyor-transfer points, 400 each; total 7,300 cu. ft. per min. Suction fan at 175 r.p.m. drew 7,300 cu. ft. per min. at 6.35-in. water pressure. Power was provided by one 20- and three 1-hp. motors. Velocity of air in collecting pipes was 3,000 ft. per min. Filter plant comprised 260 @ 11 $^1/_2$×75-in. Sly bags, with a total area of 4,900 sq. ft., or 1.5 cu. ft. of air per min. per sq. ft. of bag area. The fan operated 84 min., then stopped for 1 $^1/_2$ min. while the filter beaters operated, when it started again automatically. Dust discharge was continuous. Two tons of dust, assaying 0.10 oz. Au, was collected per 16 hr., a recovery of $7.00 per day. Cost per year was: labor, $188; renewals, $345; or $1.50 per day. Net saving per year was $1,900. The dust collected was 97% $<$ 325-m. Fan discharge averaged 230 $< 5\mu$ particles per cc. Cost of plant: materials and machinery, $8,146; labor, $2,218; or $55–$60 per ton of feed per hr. Volume of crushing plant building is 453,220 cu. ft. Renewals included about 200 bags per year.

At MOUNT ISA, 1,500 tons is crushed per 8 hr. from run-of-mine to $< ^3/_4$-in. Volume of air: 7,500 cu. ft. per min. from under two 24×36-in. crushers, two grizzlies, and one conveyor-exit; it is taken by 19-in. pipes (at 45° slope) to one 7-ft. cyclone and fan; 3,000 cu. ft. per min. is taken (at 25°) to one 7-ft. cyclone and fan from two 5 $^1/_2$-ft. Symons cones and one conveyor exit. Total 10,500 cu. ft. per min. requires two 17-hp. motors. Velocity of air in collecting pipes is about 3,750 ft. per min. Two Spenstead filters, 8 ft. diameter, with 37 @ 14-in. × 14-ft. bags, or 1,632 sq. ft. each (3.1 cu. ft. of air per min. per sq. ft. of bag area), precipitate the dust.

For installation at MORENCI see Sec. 2, Fig. 29.

12. SHOPS, REPAIRS, SUPPLIES

Character of shop work. At an operating mill, shop work is confined almost exclusively to repairs; while a mill is under erection, however, the shops are a most valuable adjunct, and may well be the first buildings set up. A long, simple structure can be partitioned off, the most convenient arrangement being, starting at one end: office, warehouse, machine shop, carpenter shop. Blacksmith work can usually be done most conveniently at the mine shop. The scope of work to be arranged for depends on the size and elaborateness of the mill, and its situation with respect to other established shops capable of doing at least some of the required work. The foundries and machine shops of an enterprise like UTAH COPPER Co., for example, providing for the operation of mines, railroad, and two large mills, compare favorably as to size, arrangement, and completeness with the best industrial machine works. A small mill in an outlying district would be justified in the installation of fairly complete shop machinery, even if not all continuously occupied, so as to save time in repairs and avoid some duplication of expensive mill equipment to guard against delays. Some means of transferring parts of heavy mill equipment into the shop without excessive effort must be provided by car tracks, crane, or both.

List of equipment for a MACHINE SHOP for a small mill: Hand punch and shear; lathe, 18-in. swing, 8- to 10-ft. bed; pipe-threading machine, 1 $^1/_4$ to 4 in.; oxyacetylene torch outfit complete; bolt- and pipe-threading machine for $^1/_2$- to 1 $^1/_2$-in. bolts and $^3/_8$- to 1-in. pipe; electric- or air-driven hand drill; portable forge, anvil and blacksmith tools; radial drill press, 48-in.; power hack saw. The usual assortment of hand tools, vises, benches, etc. The CARPENTER SHOP, besides benches and hand tools, should have a saw bench with 16-in. circular saws and a buzz planer.

At one large mill in the Southwest, the following machine tools, all with individual motors, are installed: 27-in. × 28-ft. lathe, 14-in. × 12-ft. lathe, 6-ft. radial drill, 16-in. spindle drill, 28-in. swing drill, 100-in. boring mill, 42-in. × 12-ft. planer, 24-in. shaper, No. 2 and No. 6 pipe machines, friction

saw, punch and shears, blacksmith forges, welding equipment. One 5-ton crane serves these machine tools. A 5-ton crane and a 60-ton crane with a 10-ton auxiliary are installed over the secondary ball mills to carry loads from the mill to the machine shops which are near by.

Repairs, in most cases, must be made without moving the machine from its place; small repairs can be made by the mill crew, who should be provided with benches and hand tools at convenient places in the mill. Worn parts of crushing machines can usually be repaired more conveniently in the shop, where screw jacks, hydraulic presses, etc., are available. With such machines, the best practice is to keep one or more spare parts on hand, assembled and ready to install; this applies particularly to gyratory spindle and crushing head, rolls, cylinder-mill scoops, and entire mills.

Cranes or crawls are essential in every part of a mill containing equipment too heavy to be lifted by rope or chain tackle and temporary staging; they also avoid the trouble and delay in erecting the latter, even where they might be strong enough. The usefulness of a crane begins while a mill is under construction, and it should be installed as soon as the columns and beams are in place. Care should be taken to insure that the crane is able to reach every unit of equipment it can advantageously serve, including motors, tumbling-mill scoops, classifiers, heads of elevators, and pumps, in addition to the heavier crushing equipment. A crane should also be able to travel either into the repair shop or far enough to deliver its load to a car or another crane serving the shop; if possible, the cranes in those parts of a mill having the heaviest equipment should reach also the railroad or supply yard.

Cranes are found serving the crushing plant and tumbling-mill floors at most large plants and at many of the smaller plants. The flotation floor is crane-served at the Utah Copper Co. mills because of the necessity for lifting out the 10- and 6-hp. vertical motors to change impellers. At the United Comstock (*114 J 846, 117 J 516*) the coarse-crushing department, containing No. 7 1/2 gyratories, 72-in. rolls, and 200-hp. motors, has a 20-ton crane reaching the railroad and the working space between the shops; the fine-crushing section, with 7×6-ft. ball mills and 150-hp. motors, also has a 20-ton crane traveling over the supply yard and into the shops; the cyanide department, with basket filters aggregating 74,400 sq. ft. of filtering surface, contains two 40-ton traveling cranes. The Copper Queen had an unusually complete equipment of electric cranes, comprising two double-hoist 60-ton @ 30-ft. span, one 50-ton @ 75-ft. span, two 20-ton @ 38-ft. span, two 5-ton with 37- and 29- ft. spans respectively.

Hand-operated chain blocks are available with lifting capacities up to 20 tons and reaches up to 18 ft.; small, self-contained electric hoists, for suspending from girders, have capacities up to 10 tons with a lift of 10 ft. The simplest crawl consists of a 4-wheel trolley truck running on the lower flange of an I-beam; trolleys for loads up to 10 tons are on the market.

Warehouse and supply department is essential to efficient operation; under competent administration it reduces waste, facilitates cost accounting, and avoids loss of operating time resulting from lack of necessary materials. The warehouse should adjoin the railroad and be as close as practicable to the mill and shops. Materials regularly consumed, such as balls and pebbles and flotation reagents, should be stored near the point of consumption, though still under the jurisdiction of the storekeeper; other supplies, used intermittently, should be kept in the storehouse and issued only on requisition. Paints, lubricating oils, and similar highly inflammable materials should have separate fireproof storage. Lumber, lime, and cement should be protected from weather.

The quantity of supplies and spare parts best kept on hand depends on plant location, transportation facilities, and local conditions governing the time required to obtain shipments; also on the size, type, and financial status of the operation. To obtain lowest insurance rates, shops and warehouses should be located at least 50 ft. from the mill building.

A most important feature of stores operation is a correct running inventory, kept for the dual purpose of having material on hand when required yet keeping the money thus tied up at a reasonable minimum. The store balance should be checked accurately against the running record at least once a month.

13. METHODS OF PRACTICAL DESIGN

Preliminary layout. A flowsheet is the first requisite. This must have been exhaustively studied and thoroughly and finally decided upon in respect to every important detail, including number, types, sizes, and capacities of individual machines; their relative positions with respect to one another; quantities of ore and of water in transit at every point throughout the mill; power required by every machine; and number, sizes, and types of all motors and the speed reducers connected with each. The design of the flowsheet will be based on the results of laboratory or pilot mill experiments, interpreted in the light of experience, and will be guided by the available supply of water, sources of power, type

of mill structure applicable to the site, and other practical considerations. A TOPOGRAPHIC MAP of the site is required, not only to select the general type of structure, but to determine the amount and character of the required excavations and the placing of walls, foundations, etc., so as to reduce the amount of this work, after the manner of a railroad location. The map, which will usually have been made early in the investigation, should cover a sufficient area to allow a choice among equally accessible sites and permit the final and precise selection to be deferred until the more important structural features have been determined. PRELIMINARY SKETCHES in three projections, not necessarily to scale, are a valuable means of crystallizing ideas, gaining a sense of proportion, and transmitting suggestions for execution of the next step. PRELIMINARY SCALE DRAWINGS should be confined to outlines, preferably on a scale of $^1/_{20}$ in. to the foot; adoption of this small scale protects the draftsman from the constant temptation to go too far into detail, thereby obscuring general features. The three projections of these drawings should appear on a single sheet, so as to give better idea of space proportions. On these drawings, the draftsman should prepare and make constant use of templates representing the outlines of individual machines or groups of closely related machines, such as rolls, elevator and trommel; ball mill, motor and classifier; these templates (used under transparent paper) not only save much time during the initial period when erasures are likely to be frequent, but are of great assistance in fixing the most advantageous position of the equipment. PRELIMINARY ESTIMATES of structural elements can be made from these small-scale drawings. These estimates, as well as those that follow, and all calculations on which they are based, should be preserved in bound notebooks (conveniently 8 × 10 in. or larger).

Detailed general drawings, in three projections on a scale of $^1/_8$ to $^1/_4$ in. to the foot, depending on over-all dimensions, must be complete as to every item, and show as much detail as possible at that scale. Nothing having any bearing on the erection of the building and installation of machines should be omitted; the more complete these drawings, the quicker the construction can be finished and the less the chance for overlooking essential features. Among the items that must be plainly shown on the general drawings are: foundations and floors, frame, walls and roof, windows, cranes and crawls, all machinery, motors and drives, shafting, clutches and pulleys, launders and pipe lines. A small mill should be drawn in entirety, a separate sheet for plan, front elevation, and end elevation or sections; for a larger mill, a typical unit will suffice at this larger scale, if accompanied by a complete assembly at a smaller scale.

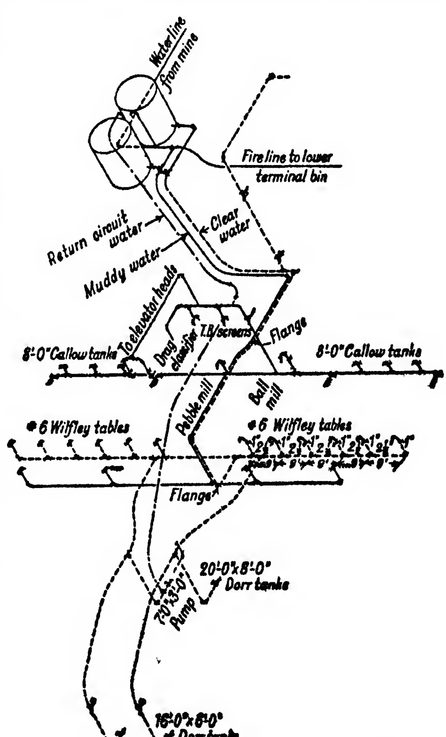

FIG. 32. Typical arrangement for layout of mill-water piping.

Construction details. The amount of large-scale drafting of structural details depends upon the size of mill and type of construction. The following detailed drawings should be supplied for all mills: (*a*) EXCAVATIONS: volume and character. (*b*) FOUNDATIONS: footings, dimensions and batters, copings, reinforcements, drains or "weep" holes, elevations of the top of each wall, pier or foundation above the datum plane, and the position of anchor bolts. (*c*) MECHANICAL EQUIPMENT: where machines of standard types and sizes are adopted, dimensions and foundation plans of which are supplied by manufacturers, the drawings to be made for construction purposes will relate mainly to their support and the facilities for conveying ore to and from them; for the installation of the large variety of other equipment, such as trommels, elevators, conveyors, feeders, distributors, samplers, and all other devices that must be adapted in size and arrangement to suit the particular mill, completely detailed

drawings should be prepared, including their connecting elements. (*d*) SHAFTING and all its appurtenances, including hangers or pillow blocks, journal boxes, clutches, pulleys, collars, and couplings; descriptions of all these elements should appear as completely as possible on the drawings, so that the accompanying written specifications need be little more than a reference list. (*e*) PIPING SYSTEM as a whole can be shown most easily and clearly by an isometric projection (see Fig. 32), on which the dimensions of all main and branch lines, valves, and fittings can be indicated; for minor details of particular connections, a sketch on larger scale should be appended as an insert on the main drawing. (*f*) LAUNDER SYSTEM must be worked out in all its details and subjected to careful scrutiny as to the ability of each member to carry the desired volume of its given pulp; this is a particularly important feature of design, and should not be left to the discretion of the millwright, since a launder once installed at too low a slope is difficult to reconstruct. (*g*) WIRING DIAGRAM, conveniently indicated by colored lines on a copy of the general drawings, should state the sizes of conductors, character of insulation, position of switches, fuses, lights, etc.

Arizona concentrators	Ariz.		T, F	1,000					

a A, amalgamation; C, cyanidation; F, flotation; J, jig; M, magnetic concentration; R, rolls; Rg, roasting; SF, selective flotation; T, tables; W, washing.

b Includes electrical and miscellaneous; the former usually amounts to 10 to 15% and the latter to 4 to 5% of total cost of all machinery, f.o.b. factory.

c Excluding power-generating plant.

d Capacity 1,000 tons, equipped for 500 tons.

e Includes installation of machinery.

f Installed.

Steel structures. It is rarely necessary for the mill designer to prepare detailed structural drawings for steel work. If the plant can be protected by one or a group of simple rectangular buildings, these can be purchased ready-made from a number of fabricators. For a larger and more complicated structure, the usual procedure is to prepare several sets of general plans, accompanied by a statement of the roof-load, floor-load, crane-capacities, character of wall material, etc., and submit these to steel-work fabricators, who thereupon assume responsibility for detailed working drawings. Bids and weights from these fabricators are scrutinized and compared, and the low bids carefully checked before contracts are awarded.

Wooden structures. If time permits, it is helpful to provide the millwright with a separate set of drawings of the structure dissociated from the mechanical equipment; this is easily done by tracing from the general detailed plans. If time is short, a set of the general plans can be amended by addition of dimensions and such details as are not shown with sufficient clearness for the millwright's use, notably trusses and bins.

g Unspecified items added to make total check.
h Sulphide and oxide.
i Graphite.
j Asbestos-covered.
k Including shops and warehouse, but not tailing-disposal plant.
l Excluding excavation and concrete work.
m Includes labor on building.

14. METHODS OF COST ESTIMATING

A preliminary, approximate idea of the ultimate cost of a complete mill of given type may be gained from the following factors, representing in round numbers the range in total cost of erection and installation per ton-day (24-hr.) capacity:

Jig-table mill, Tri-State district, buying electric power	$100– 150
Coarse concentration, jigs and tables	300– 450
Fine concentration, tables and flotation	600– 750
All flotation one-mineral separation	600– 800
All flotation, two-mineral separation	700– 900
Fine crushing and cyanidation	700–1,200
Stamps, amalgamation	400– 700

Table 56 gives examples of mills representing the above types.

Erection and installation. When the factory prices of all essential machinery have been ascertained, the probable cost of the completed mill can be approximated by the empirical rule that for each $1 in machinery, f.o.b. factory, the cost of erecting the building and installing the equipment will range, under average conditions, from $0.75 to $1 per dollar of machinery cost, running up to $1.50 in exceptional circumstances, such as expensive building materials, inefficient labor, and delays. (See Table 56.)

Cost-volume ratios. Under average conditions in United States mining districts, the cost for labor and materials of buildings alone will approximate, per cubic foot of enclosed space: Wooden buildings, 8 to 12¢; steel buildings, 15 to 20¢. (See Table 56.)

Erection, labor-cost factors. Based on the quantity of principal structural material required, the cost of erection can be estimated roughly as follows: Wooden structure, $35 to $45 per M bd. ft.; steel structure, 1.0 to 1.5¢ per lb. Based on tons of equipment installed, the labor cost alone, covering the erection of building and installation of machinery, may be estimated at roughly $100 to $110 per ton for ordinary plants in locations not too isolated; plants in the tropics requiring little more than a shed for housing may fall to $50 per ton; complicated plants in remote regions may run above $200 per ton (1940) (See Table 56.)

Equipment costs. Factory prices (1938), weights, and labor costs of erection of individual machines are given in Table 57. These prices, especially the labor costs, which will vary with local conditions and wages, are approximate only and are intended for preliminary estimates. Final estimates should be based on quoted prices.

It is intended that the following list shall be used for estimating purposes only. To the factory price of machinery should be added enough to cover (*a*) freight charges from factory to the railroad point nearest the mill (approximately $1.50 per 100 lb., or say 2¢ per ton-mi. for carload and twice as much for less than carloads), (*b*) the cost of hauling from railroad to millsite (say 40¢ per ton-mi. for teams or 20¢ per ton-mi. for motor trucks), and (*c*) the cost of unloading and distributing machinery on the millsite (about $3 per ton). It should be borne in mind also that some manufacturers list prices that are intended to form an initial basis for bargaining.

Excavation that was required at several mills and the cost per cubic yard are given in Table 58.

Concrete work, its volume and cost, covering walls, foundations, and floors at typical mills, is shown in Table 59.

Final estimates are based on completed plans and specifications, previously described (Art. 13). The first step is to prepare an ITEMIZED LIST of all equipment and materials required; much depends on the completeness of this list; nothing should be omitted that will contribute in the least degree to the satisfactory operation of the mill. Some of the items most likely to be overlooked are given in the following list:

Building rods, bolts, washers, drift spikes, etc.; blower air piping; brick; belt fasteners; cranes, hoists, trolleys; chain blocks and crawl beams; condensation-water tank and pump; cleaning up; construction tools; ditch digging; electric lighting, power poles, light wiring, conduits, and connections; equalizing-water tank and float; elevator bolts, washers, etc.; feed distributors; fuel for heating mill during construction; fire protection; fire hose; grinding balls; gear housings; linings for launders, etc.; lighting: drop cords, shades and globes, transformers; lime bins and feeders; master valves; oil and waste; power cables; piping, all necessary fittings, etc.; paint and painting; reagent storage, feeders; repair parts and renewals; screen coverings; steam heating; steel chutes; sampler equipment; stairs; signal system; steam-pipe coverings; stock-tank agitators; windows; walkways and guard rails; water mains; water-supply tanks; water-supply pumps.

Table 57. Weights, factory costs, and labor costs for erecting the principal items of mill equipment

Equipment	Factory weight, lb.	Factory price, 1938 *a, b*	Labor cost of erection	Remarks
Acetylene cutting and welding outfit	1,195	$775	....	Incl. generator and truck.

a Included with cement.

Underestimating the cost of a proposed job is invariably due to failure to list properly all the items composing the installation and the work to be done to complete the plant to the point of actual operation. Care in this particular is really more important than precision as to each item, for in the very long list of items always needed, individual errors will tend to compensate.

The list should next be SEGREGATED according to the character and source of the materials: ore-dressing equipment (further subdivided as to specialties offered by particular manufacturers); motors and electric appliances; shafting, pulleys, clutches, speed reducers, etc.; belts; piping, valves and fittings; lumber; roofing and siding materials; windows;

Table 60. A form of cost estimate

PRELIMINARY ESTIMATE AND FINAL SUMMARY

		Totals D–L	2,907.0	....	$212,080	51.8	
M	60	Engineering & Expenses	7 1/2% on $380,530		$ 28,540	7.0	
A–M		Grand totals	3,592.0	$114.00/ton	$409,070	100	464.5

Ratio A, B, C machinery costs to all other costs: $\frac{\$240,620}{\$168,450} = \$1 : \$1.43$

Total labor bill per ton of machinery installed: $\frac{\$63,760}{685} = \$93$ per ton of machinery

Total cost of plant per 24 hr.-ton of ore treated: $\frac{\$409,070}{200} = \$2,045.35$ per 24 hr.-ton

Hp. per 24 hr.-ton of ore treated: $\frac{464}{200} = 2.32$ hp. $= 41.5$ kw.-hr. per ton

paints; structural steel work (not usually necessary to list in detail—see Art. 13); boilers; engines. Bids are then invited from manufacturers of the respective classes, stating weights, prices, and time of delivery. Bids should be scrutinized, not only as to prices and quality, but also to insure that each one covers exactly the amount and kind of material wanted; freight charges to the millsite may affect comparison of factory prices. A convenient form for final presentation is suggested in Table 60, in which different items are definitely segregated. Machinery should be subdivided as to principal, electrical, and miscellaneous, all f.o.b. factory. Labor should comprise all labor, namely: erecting principal, electrical, and miscellaneous machinery, steel work and lumber, mixing and placing concrete, handling and moving machinery at millsite. Freight and hauling should include all charges of this kind between the factory and millsite. This generalized tabulation should be supported by full and complete lists covering every item, giving factory costs and weights, gross or shipping weights; also horsepower in detail. Following the same

segregation as above, but in more detailed form, volumes of excavations and foundations, steel, lumber, cement, concrete aggregate, etc., should be tabulated; similarly, all other constructional materials. An accompanying tabulation should also express the final estimates departmentally, as for instance, coarse-crushing, fine-grinding, concentrating, flotation, and cyanidation; also transformer station or powerhouse, machine shops, warehouse, water supply, and tailing.

SECTION 21

MATHEMATICS

BY

PERCEY F. SMITH, EMERITUS PROFESSOR OF MATHEMATICS,

YALE UNIVERSITY

ARITHMETIC

Numerical engineering data are rarely accurate to the extent that is implied in numbers viewed in absolute mathematical sense.

1. APPROXIMATE COMPUTATION

Significant figures (**1**) * are those digits of a number concerning which accurate and approximate knowledge are, respectively, avouched. Number 6,347 has four significant figures. Digits 6, 3, and 4 are impliedly accurate and in proper order; the 7 implies only that the truth is nearer to 7 than to 6 or to 5. Number 0.6347 avouches that the truth lies between 0.63465+ and 0.63475− units: the number 634,700 warrants the truth to lie between 634,650+ and 635,750−. A significant number ending in an even digit implies a possible range of $+{}^1/_2$ in the last significant digit, *i.e.*, 5,376 implies a range in value from 5,375.5 to 5,376.5, whereas 5,377 implies a range of ± 0.4, *i.e.*, from 5,377.4 to 5,376.6; because final 5's are ROUNDED OFF to make the preceding digit even.

Fundamental arithmetic calculations. Since the last digit in any significant number is doubtful, any result into which it enters is doubtful. Retain in a sum or difference only those digits from columns in which all digits are significant. Retain in a product only those numbers not resulting from multiplication by the final significant figure in that factor with the smaller number of significant figures. In general, the number of significant figures in a product will be equal to, or one more than, the lesser of the numbers of significant figures in the factors, according to whether the multiplication of the left-hand numbers of the factors adds a digit (is >10 with the carry over). Retain in a quotient as many significant figures as there are in the lesser of the dividend and divisor.

* Boldface figures in parentheses in text refer to items in *Bibliography*.

Accurate numbers. If either factor in a multiplication or division is accurate, the product or quotient is significant to the extent that it includes the last figure to the left that has been involved with a doubtful number.

Errors in tables. The numbers in the usual mathematical tables, and those in substantially all engineering tables, are approximations, rarely accurate in the last digit, and frequently, in engineering tables, not significant in the last two or more digits. Since multiplication always, addition usually, and subtraction and division in some instances cumulate errors, results must be studied carefully to determine the extent of significance.

Rules of error. In a sum or difference the ABSOLUTE ERROR (actual difference between approximate and actual values) of the result is not greater than the sum of the absolute errors of the entering terms.

In a product or quotient the relative error (ratio of absolute error to exact value) is not substantially greater than the sum of the relative errors of the terms.

Interpolation in tables is based on the assumption that the variation between tabular intervals is linear (Art. 9). Error in the interpolated result depends upon the tabular interval and the function tabulated; in five-place mathematical tables it is rarely greater than one unit in the last figure.

LOGARITHMS

The logarithm of a given number a is the power to which some constant number (base) must be raised to produce a. The base of the usual tabular logarithms is 10. Hence if $a = 10^m$, $\log a = m$, which may be less or greater than 1.0 and is usually a MIXED (not a whole) NUMBER. Tables of logarithms give the decimal part of the logarithm (MANTISSA); the number preceding the decimal point (CHARACTERISTIC) is determined by the magnitude of the given number.

Simple formulas for use of logarithms. If a and b are any given numbers

$$\log (a \times b) = \log a + \log b$$
$$\log (a/b) = \log a - \log b$$
$$\log (a)^n = n \log a$$
$$\log \sqrt[n]{a} = (\log a)/n$$

Rules for characteristic. The characteristic of a whole or mixed number is one less than the number of digits preceding the decimal point, and is positive. The characteristic of a decimal fraction is negative and equal to one more than the number of ciphers preceding the first significant figure.

Logarithm of a number is the sum of the mantissa and the characteristic. Its positive or negative character is determined by the sign of the characteristic only; the logarithm of a negative number is the same as that of the same number positive ($\log(-8) = \log 8$).

To find the logarithm of a number, first set down the characteristic by inspection (Table 1), then find the mantissa from tables (*e.g.*, Sec. 22, Table 20). (Such tables are designated 4-place, 5-place, etc., to indicate the number of significant figures in the mantissa, and the maximum number of significant figures in the result that they yield. The entry number has two less digits than the number of places.) Enter with the first digits of the given number, proceed horizontally to the vertical column corresponding to the digit following the entry digits, add to the number there found the number from "Proportional parts" corresponding to the next digit (rounded off) of the given number; the sum is the required mantissa.

Example 1. Wanted log 4,128. Characteristic = 3. Mantissa (from Table 20, Sec. 22): Enter at 41, proceed horizontally to column headed "2," add to the last digit of 0.6149 there found the number 8, found in column 8 under "Prop. parts," giving 0.6157. Add this to characteristic, whence log 4,128 = 3.6157.

Example 2. Wanted log 0.0002953. Characteristic (Table 1) is −4. Mantissa, considering sequence of significant figures without regard to preceding ciphers, is 0.4702 (see Ex. 1). Log $= -4 + 0.4702 = \bar{4}.4702 = 6.4702 - 10$. The final form is normally used for convenience in calculation (see p. 03).

Table 1. Characteristics of logarithms and cologarithms

Characteristic of logarithm	Number	Characteristic of cologarithm
	4 3 2 1 . 1 2 3	
3	6 7 4 2 .	6 − 10
2	6 7 4 . 2	7 − 10
1	6 7 . 4 2	8 − 10
0	6 . 7 4 2	9 − 10
9 − 10	0 . 6 7 4 2	0
8 − 10	0 . 0 6 7 4 2	1
7 − 10	0 . 0 0 6 7 4 2	2
6 − 10	0 . 0 0 0 6 7 4 2	3
	etc.	

Cologarithm of a number is the logarithm of the reciprocal of the number. Since $a/b = a \times 1/b$, $\log (a/b) = \log a + \operatorname{colog} b$.

To find the cologarithm of a number: (1) Find the logarithm and subtract from zero (= log 1). Colog 4,128 = 6.3843 − 10 = $\bar{4}$.3843. Colog 0.00002953 = 4.5298. (2) Set down characteristic by inspection and get mantissa from table of logarithms of reciprocals (Table 22, Sec. 22). Characteristic of the cologarithm of a whole or mixed number is equal to the number of digits preceding the decimal point, and is negative; that of a decimal fraction is positive and equal to the number of zeros preceding the first significant figure (see Table 1). Mantissa is found from the table as for the mantissa of a logarithm, *except* that proportional parts are subtracted.

Antilogarithm ($\log^{-1}$) is the number corresponding to a given logarithm. To find: locate the mantissa of given logarithm in usual log tables and read corresponding number; place decimal point according to characteristic. Table 23, Sec. 22, entered by the given mantissa, reads the digit sequence of the desired number directly.

Calculation with logarithms. Most arithmetic calculations are based on the simple formulas (p. 02).

Multiplication. Find logarithms of numbers, add them; find antilogarithm of sum. Point off to correspond with characteristic.

Example: Multiply 3,923 by 0.00007218

log 3923	= 3.5936
log 0.00007218	= 5.8584 − 10
log product	= 9.4520 − 10
$\log^{-1}$	= 0.2831 *Ans.*

Division. Find logarithm of numerator; find cologarithm of denominator; add; find antilogarithm of sum. Point off to correspond with characteristic.

Example 1. Divide 3,923 by 0.00007218

log 3,923	= 3.5936
clg 0.00007218	= 4.1416
log quotient	= 7.7352
$\log^{-1}$	= 54,360,000 *Ans.*

Example 2. Divide 0.00007218 by 3,923

log 0.00007218	= 5.8584 − 10
clg 3,923	= 6.4064 − 10
log quotient	= 12.2648 − 20
$\log^{-1}$	= 0.00000001840 *Ans.*

Powers. Find logarithm of number; multiply by power; find antilogarithm of product. Point off to correspond with characteristic.

Example 1. Compute $(2{,}953)^2$

log 2,953	= 3.4702
Multiply by 2	= 6.9404 = log result
$\log^{-1}$	= 8,718,000 *Ans.*

Example 2. Compute $(0.2953)^2$

log 0.2953	= 9.4702 − 10
Multiply by 2	= 18.9404 − 20 = log result
$\log^{-1}$	= 0.08718 *Ans.*

Example 3. Compute $x = (2{,}953)^{3.672}$

log x	= 3.672 × (log 2,953)
log 2,953	= 3.4702
Multiply by 3.672 (Use logarithms)	
log 3.470	= 0.5403
log 3.672	= 0.5649
log log result	= 1.1052
$\log^{-1}$ log result	= 12.75 = log result
$\log^{-1}$	= 5.6×10^{12} *Ans.*

Example 4. Compute $x = (0.02953)^{0.03672}$

log x	= 0.03672 (log 0.02953)
log 0.02953	= 8.4702 − 10
	= −2 + 0.4702 = −1.5298
log −1.5298	= 0.1847
log 0.03672	= 8.5649 − 10
log log x	= 8.7496 − 10
log x	= −0.05618 (= −1 + 0.9438)
	= 9.9438 − 10
x	= 0.8788 *Ans.*

Multicomponent fraction. Find logarithms of components of numerator and cologarithms of components of denominator; add; find antilogarithm of sum.

Example. Compute $x = \dfrac{3.62 \times \sqrt{9{,}349} \times 0.6218 \times (728.7)^3}{\sqrt[3]{43.29} \times 86.2 \times 0.0003294 \times (3.32)^4}$

log 3.62	= 0.5587		0.5587
log 9,349	= 3.9707	½ log 9,349 =	1.9854
log 0.6218	= 9.7937 − 10		9.7937 − 10
log 728.7	= 2.8625	3 log 728.7 =	8.5875
clg 43.29	= 8.3636 − 10	⅓ clg 43.29 =	9.4545 − 10
clg 86.2	= 8.0645 − 10		8.0645 − 10
clg 0.0003294	= 3.4823		3.4823
clg 3.32	= 9.4789 − 10	4 clg 3.32 =	37.9156 − 40
log x	=		79.8422 − 70
x	= 6,953,000,000		
	= $6.953 \cdot 10^9$ *Ans.*		

Errors. In computations such as are illustrated above, errors in final logarithms are introduced which may be appreciably greater than the error of the tables. The latter may be assumed to be not greater than half a unit in the last decimal place, although it may, by interpolation, be a whole unit at times. Hence, for example, in raising a number to fifth power, an error of five units may occur in the final logarithm and this may lead to an error, in the number itself, of one unit in the third significant figure. Computation with four-place tables does not ensure more than three-figure accuracy. Tables

with mantissas carried out to five or more places are essential for accuracy to four or more significant figures. Such tables are available in great variety (**2**).

Natural, or Napierian, logarithms. The base of this system is 2.71828 . . . (to five places), denoted by e. $10^{0.43429 \cdots} = 2.71828$. Common logarithm equals the natural logarithm times 0.43429, which number is called the MODULUS of the common system. Natural log = common log times 2.3026. The abbreviation NAP LOG or LN is used for natural or Napierian logarithm.

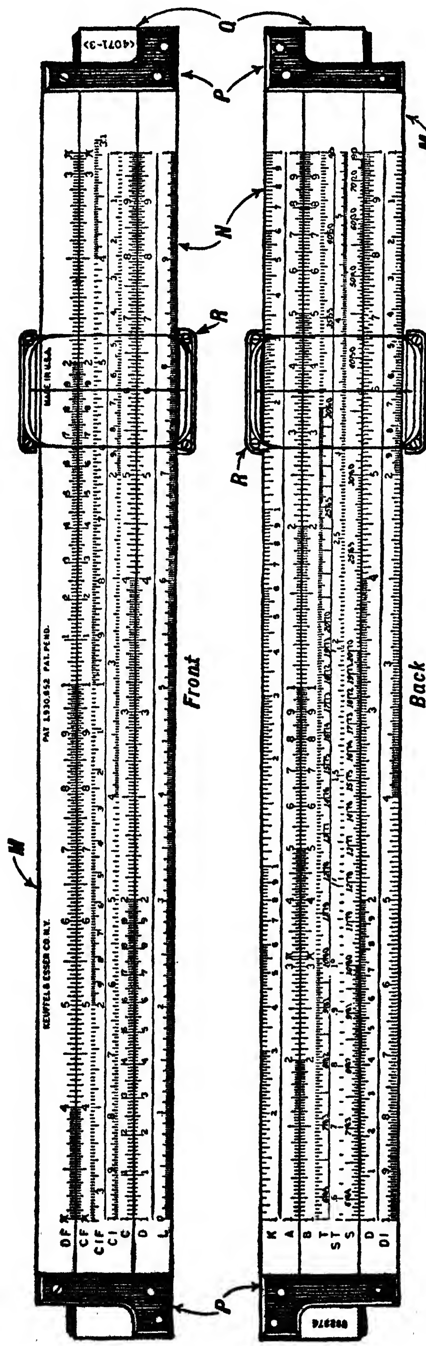

FIG. 1. Polyphase duplex Decitrig slide rule. (*Courtesy Keuffel & Esser Co. of New York.*)

Slide Rule

Description. The slide rule is essentially a mechanical device for adding, subtracting, multiplying, and dividing logarithms, and thus performing the same calculations as those illustrated on p. 03. Fig. 1 illustrates a convenient form. It consists of a frame comprising two bars M and N, rigidly fastened together by end members P; a single slide Q; and a single runner R. Bars M and N and slide Q are ruled both sides with a variety of scales; runner R carries two hairlines (one on each face of the rule) in registry with each other. Standard length is 10 in. (10-in. rule); 5-in. and 20-in. rules are readily available; rules with lengths of several feet are made by winding the scales spirally on cylinders. Accuracy in setting and reading increases with length of scale (**3**).

Scales C and D (Fig. 1, front) are logarithmic, *i.e.*, the logarithms of numbers from 1 (log = 0) to 10 (log = 1) are laid out to a linear scale (10 in. long on a 10-in. rule) and the points are labeled with the numbers. If, now, 1 on the C-scale is brought to, say, 2 on the D-scale, and any number, say 2, on the C-scale is selected, the distance on the D-scale from 1 to the point now corresponding to 2 on the C-scale is the logarithm of 2 (distance 1 to 2 on the D-scale) plus the logarithm of 2 (1 to 2 on C-scale = distance 1 to 2 on D-scale). This sum is log 4, and is labeled 4 on D-scale. The rule has thus added log 2 + log 2, and given the product $2 \times 2 = 4$. Similarly, if any point, say 2, on the C-scale is brought to any other point, say 6, on the D-scale, and the reading on D corresponding to 1 on C is taken, it will be seen that the distance from this point to 1 on the D-scale is log 6 minus log 2, and that the difference on the D-scale is marked 3 (*i.e.*, = log 3), so that the rule has divided 6/2 to give the answer 3. It makes no difference which 1 on the C-scale falls on the D-scale in these manipulations; the rule acts the same as though the C- and D-scales were laid out on a circle of 10 in. circumference, with the two 1's on each scale coincident (such rules are made).

Scale A **(Fig. 1, back) is a double logarithmic scale, and scale** K **a triple logarithmic**

scale, comprising respectively two and three scales from 1 to 10, set end to end in a 10-in. over-all length. The initial (left-hand) and final (right-hand) 1's on the D-, A-, and K-scales are all in vertical registry. Hence the logarithmic distance traversed along scale A for any given movement of the runner is twice that traversed on scale D, *i.e.*, scale A multiplies the logarithms of scale D by 2, and thus squares the numbers of scale D. Conversely the numbers on scale D are the square roots of those on scale A. Similarly the numbers on scale K are the cubes of those on scale D, and those on scale D are the cube roots of those on scale K. Again, the numbers on scale K are the 3/2 powers of those on scale A, and those on scale A are the 2/3 powers of those on scale K.

Scale DF (D-folded) may be considered to be made by cutting scale D at the value for π and then joining the parts so that the 1's at the ends of original scale D exactly coincide. The scale is mounted so that the value π is in registry with the values 1 and 10 of scale D. The result is that all numbers on DF are π times those in vertical registry on D; conversely those on D equal those on DF divided by π. Scale CF is the same as scale DF, and hence bears the same relation to scale C that DF bears to D, and the two folded scales bear the same relation to each other as do C and D.

Scale CI (C-inverted) is the same as scale C except that it is laid out from right to left on the slide. Hence its readings are the reciprocals of those on the C-scale. Similarly, CIF (C-inverted folded) is the same as CF except that it runs from right to left. Both of these scales are numbered in red to warn that they must be read in the unusual (right-to-left) direction.

Scale L is a scale of logarithms when it is read in connection with scale D. Actually it is a simple linear scale marked into inches and fiftieths. Numbers thereon, when read in accord with the scale markings and preceded by a decimal point, are mantissas of the logarithms of the numbers on scale D.

The S-scale (sine scale), when in registry against scale A, gives the angles corresponding to the numbers on scale A, taken as decimals, those on the left-hand half of the A-scale being read with a cipher before the first significant figure. Conversely the sine of angles from approximately 34′ to 90° may be read on A above the corresponding angles on S when the scales register. Thus sine 40′ is 0.0116; that for 4° is 0.0698; for 6° is 0.1045; and for 20° is 0.3420.

The T-scale (tangent scale) similarly gives values for the tangents of angles from about 6° to 45° when read against the D-scale. For angles greater than 45° use the formula $\tan (90 - x) = 1/\tan x$. Thus tan 40°, read directly on D, is 0.839. $\tan 60° = 1/\tan 30 = 1/0.577 = 1.732$. For angles less than 5° 43′, sine = tangent with sufficient accuracy for slide-rule calculation.

Common Slide-Rule Calculations

Multiplication. (a) Set 1 (either end) of C to one factor on D; set runner over other factor on C; read product under hairline on D.

(b) Set 1 on CF to one factor on DF; set runner to other factor on CF; read product under hairline on DF.

(c) Set 1 on CF to one factor on DF; set runner to other factor on C; read product on D under hairline.

Division. (a) Set runner to dividend on D; bring divisor on C under hairline; read quotient on D under 1 on C (either end); or on DF over 1 on CF.

(b) Set runner to dividend on DF; bring divisor on CF under hairline; read quotient on DF over 1 on CF, or on D under 1 on C (either end).

(c) Set 1 on CI to dividend on D; bring runner to divisor on CI; read quotient on D under hairline. Or with the same setting of slide, bring runner to divisor on CIF and read quotient under hairline on DF.

(d) Set runner to divisor on D (or DF); set dividend on C (or CF) to hairline; read quotient on C over 1 on D (or read on CF under 1 on DF).

Proportion. For any relative positions of scales C and D, all corresponding numbers thereon (as marked, *e.g.*, by the hairline on the runner) are in the same proportion, as are also all corresponding numbers on CF and DF. Thus if 4 on D (or DF) is set at 2 on C (or CF), all numbers on D (or DF) are twice those with which they register on C (or CF); conversely, all on C (or CF) are one-half those with which they register on D (or DF).

Squares. Set runner to number on D (either side); read square on A. Numbers on left half of A-scale have an odd number of digits preceding decimal; those on right half an even number. To keep track of decimal point, unless it can be done mentally, write it as a number with one digit before the decimal × a power of 10; square the number on the rule; multiply by the square of the 10 factor.

Example 1. Compute $x = (1643)^2$. $1643 = 1.643 \times 10^3$. $(1.643)^2 = 2.72$. $(10^3)^2 = 10^6$. $x = 2.72 \times 10^6$.

Example 2. Compute $x = (0.0005431)^2$. $0.0005431 = 5.431 \times 10^{-4}$. $(5.431)^2 = 29.7$ $(10^{-4})^2 = 10^{-8}$. $x = 0.000000297$.

Square root. Mark off that part of number to left of decimal point into groups of two digits, beginning at the decimal point. Write the number as the product of the largest even power of 10 that will leave a mixed number of one or two digits before the decimal point and that mixed number. Set the runner on A to the mixed number (right-hand part of scale if this has two digits before the decimal; otherwise left end) and read square root under hairline on D. Take square root of powers of 10. Multiply the resulting two factors for square root of original number.

Example 1. Compute $x = \sqrt{694{,}371.2}$. Mark off: 69′ 43′ 71.2. This $= 69.43712 \times 10^4$. $\sqrt{69.44} = 8.33$. $\sqrt{10^4} = 10^2$. $x = 8.33 \times 10^2 = 833$.

Example 2. Compute $x = \sqrt{0.000069.44}$. Mark off (to right of decimal): 0.00′00′69′44. This $= 69.44 \times 10^{-6}$. $\sqrt{69.44} = 8.33$. $\sqrt{10^{-6}} = 10^{-3}$. $x = 8.33 \times 10^{-3} = 0.00833$.

Cubes. Set runner to number on D (either side); read cube on K. When numbers taken on D lie between 1 and 10, numbers on the left-hand third of K lie between 1 and 10, those in central third between 10 and 100, and those in right-hand third between 100 and 1,000. Hence to keep track of decimal point, write the number to be cubed as a mixed number with one digit before the decimal $\times$ a power of 10, and proceed as described for squares.

Cube root. Principle is the same as in extracting square root, but mark-off is in 3's and residual whole number may have 1 to 3 digits before the decimal.

Example. Compute $x = \sqrt[3]{8{,}321{,}749}$. Mark off and factor: $8'321'749 = 8.32\times10^6$. $x = 2.02\times10^2 = 202$.

Multicomponent fractions. Apart from the simple one-setting operations described, and those involved in one-setting uses of the L-, S- and T-scales, the commonest use of the slide rule is in solution of multiple-component fractions of the form $x = abcd \ldots /ghjkm \ldots$. There are several procedures for this solution; perhaps the simplest is as shown in the following:

Example. Compute $x = \dfrac{7.16 \times 2{,}340 \times 0.0017 \times 42.8}{9{,}276 \times 83.14 \times 0.63 \times 62.5} = 0.0000401$

To determine the sequence of numbers in the answer, set runner at 716 on D, bring 928 on C under hairline, move runner to 234 on C and bring 831 on C under hairline. The next step is to move runner to either 17 or 428 on C, but both of these are out of reach. The slide can be shifted so as to bring 1 at the left end of the C-scale to the present position of 10 (1 at right-hand end of C-scale) on the D-scale, which is 217; this brings the slide into a position where the next multiplier (17 or 428) is in reach, without changing the numerical relationships previously existing on the rule. Such procedure, however, fails to utilise the facilities of the rule. Rather set the runner at 17 on the CF-scale and then set 63 on the CF-scale under the hairline. (The reading 586 on the D-scale under 10 on the C-scale is now the same as though the slide had been shifted, as above described, the runner set to 17 on the C-scale and the slide moved to bring 63 on the C-scale thereunder.) Set runner to 428 on C and bring 625 on C under hairline. Read 401 on D under 10 on C.

Decimal point is best found by pointing off all numbers in the computation as products of numbers between 1 and 10, appending the proper powers of 10 to the fraction as multiplier, estimating the position of the decimal place by mental approximation of the resulting fraction without the powers of 10, and then shifting it to correspond to multiplication by the product of the powers of 10. Thus:

$$x = \frac{7.16 \times 2.34 \times 10^3 \times 1.7 \times 10^{-3} \times 4.28 \times 10^1}{9.276 \times 10^3 \times 8.314 \times 10^1 \times 6.3 \times 10^{-1} \times 6.25 \times 10^1}$$

$$= \text{approx.}\ \frac{\overset{1}{\cancel{7}} \times \cancel{2} \times \cancel{2} \times \cancel{4} \times 10}{\underset{2}{\cancel{9}} \times \underset{2}{\cancel{8}} \times \cancel{6} \times 6 \times 10^4} = \text{approx.}\ \frac{1}{24 \cdot 10^3}$$

$$= \text{approx.}\ \frac{100 \cdot 10^{-2}}{24 \cdot 10^3} = \text{approx.}\ 4 \times 10^{-5} = \text{approx.}\ 0.00004.$$

Multiplication by a constant multiplier. Set the runner to the multiplier on D. Bring to the runner that end of the C-scale to which the runner is nearest on the D-scale. Set the runner to all desired multiplicands in order on the C-scale and read thereunder the corresponding products on the D-scale. If the desired multiplicand is not to be reached on the C-scale, reach it on CF and read product on DF.

One dividend with a plurality of divisors. Set the end of the CI-scale to the dividend on D as in the preceding paragraph. Set runner to the divisors on CI and read quotients on D.

To divide a plurality of numbers by a given divisor. Set the runner to the divisor on D. Bring values of dividends on C under the hairline and read quotients on C over 1 or 10 on D.

Errors. Readings and settings on the 10-in. logarithmic scales are accurate to three figures in the range from 1 to 4, and can be estimated to four, but the fourth is liable to an error of 1 or 2 units; from 4 to 10, accuracy in reading and setting is one place less. Since most calculations involve both ends of the scales, the third significant figure must always be considered in doubt. Precision on the A-scale is not better than two significant figures, except perhaps in the range from 1 to 2; on the K-scale, it is probably never better than two significant figures.

ALGEBRA

Definitions. Letters denote numbers; the same letter denotes the same number throughout any given computation. ABSOLUTE VALUE of a number is its value regardless of sign. A MONOMIAL OR TERM is the indicated product of two or more numbers; *e.g.*, ab. A FACTOR is a number or group of numbers in a product. A COEFFICIENT is a factor of a product; it may consist of one or more numbers itself, and the other factor may comprise one or more numbers. Similar terms are those which are alike except as to coefficients; *e.g.*, $3a^2b$, ma^2b, $-7a^2b$. A polynomial is an expression comprising the algebraic sum of two or more dissimilar monomials; *e.g.*, $6x + 3y - 7z$. The product of a number by itself is a POWER of the number; an EXPONENT is a small number written superior to and following a number; it indicates the power of the number, *e.g.*, $a \times a \times a = a^3$. Degree of a poly-

nomial in any letter is the exponent of the highest power of that letter. Degree of a term in two or more letters is the sum of the exponents of all of the letters.

2. FUNDAMENTAL OPERATIONS

Addition. (*a*) The sum of two or more numbers of the same sign is the sum of their absolute values, preceded by their common sign.

(*b*) The sum of a positive and a negative number is the difference of their absolute values preceded by the sign of the one of greater absolute value.

(*c*) The sum of several similar terms is the product of the common term and the algebraic sum of the coefficients. $a^2x - 3a^2x + 7a^2x = (1 - 3 + 7)a^2x = 5a^2x$.

(*d*) The sum of two or more polynomials is the algebraic sum of all of the terms. It is usual to combine all similar terms in such a sum by method (*c*).

Subtraction. Change the sign of the subtrahend and add.

Parentheses. A parenthesis preceded by a plus sign may be removed without change in signs of the terms enclosed by that parenthesis. A parenthesis preceded by a minus sign may be removed provided the sign of each term enclosed by that parenthesis is changed. First rewrite the given expression removing the innermost parenthesis, and repeat until all parentheses are removed.

Example. $(5x - 6y) - [-4x + (4z - y) - 2z] = (5x - 6y) - [-4x + 4z - y - 2z] = 5x - 6y + 4x - 4z + y + 2z = 9x - 5y - 2z$.

One or more terms may be placed within a parenthesis preceded by a plus sign without changing the sign of any terms; or preceded by a minus sign provided the sign of each term enclosed is changed.

Example. $a + 2b - c = a + (2b - c) = a - (c - 2b)$.

Multiplication. (*a*) Exponent of the product of powers of a number is the algebraic sum of the powers of the factors, *e.g.*, $a^m \times a^n = a^{m+n}$.

(*b*) Product of monomials is the product of the coefficients $\times$ the product of the numbers. The sign of the product is positive if the signs of all factors are positive; it is positive if the number of factors with negative signs is even; otherwise it is negative.

Example 1. Compute $z = (3ax)(-2a^2x)(-7ax^3)$. Sign is $+$ since 2 factors are $(-)$. Product of coefficients $= 3 \times 2 \times 7 = 42$. Exponent of a's $= 1 + 2 + 1 = 4$; exponent of x's $= 1 + 1 + 3 = 5$. Hence $z = 42a^4x^5$.

Example 2. Compute $z = (-5a)(4ax)(-bc)(-3bx)$. Sign is $(-)$. Product of numerical coefficients $= 60$. Product of letter numbers $= a^2b^2cx^2$. Hence $z = -60a^2b^2cx^2$.

(*c*) Product of a polynomial and a monomial is the algebraic sum of the products of the monomial with the terms of the polynomial taken one at a time, *i.e.*, $(-2xy)(5x^2 - 2x - 4y) = -10x^3y + 4x^2y + 8xy^2$.

(*d*) Product of two polynomials. Arrange both multiplicand and multiplier in descending order of one of its letters; multiply each term of the multiplicand by the terms of the multiplier taken separately in order from left to right; add the partial products.

Example. Multiply $x^2 - xy + y^2$ by $x + y$.

$$\begin{array}{l}
x^2 - xy + y^2 \\
\underline{x + y \qquad\quad\;} \\
x^3 - x^2y + xy^2 \\
\underline{\qquad + x^2y - xy^2 + y^3} \\
x^3 \qquad\qquad\qquad\; + y^3
\end{array}$$

Division. (*a*) Exponent of the quotient of powers of a number is the algebraic difference between the exponent of the numerator and that of the denominator, *i.e.*, $a^m/a^n = a^{m-n}$.

(*b*) Quotient of monomials is the product of the quotients of the numerical coefficients and the quotient of the numbers. The sign of the quotient is negative if the signs of numerator and denominator are different; otherwise it is positive.

Example. Compute $w = -36a^4xb^8n/9a^3xb^7z^2$. Sign is $(-)$. Common letters are a, x, b; their exponents are a^{4-3}, x^{1-1}, b^{8-7}. The letters not common are repeated in the quotient in their original positions and powers. Hence $w = -4abn/z^2$.

(*c*) Quotient of a polynomial by a monomial is the algebraic sum of the quotients of the separate terms of the polynomial with the monomial.

Example. $(15a^2b^2 + 9a^4b^3 - 30a^6b^4)/(-3a^2b^2) = -5 - 3a^2b + 10a^4b^2$.

(*d*) Quotient of polynomials. Arrange dividend and divisor in order of descending powers of one letter. Divide the first term of the dividend by the first term of the divisor and write the result as the first term of the quotient. Multiply the entire divisor by the first term of the quotient, write the result under the dividend, and subtract. Treat the remainder as a new dividend, and proceed as before, obtaining second term of divisor. Continue until the remainder is zero, or of lower degree than the divisor in the letter of arrangement.

Example. Divide $16x + 12x^3 - 15 - 22x^2$ by $2x - 3$.

$$\begin{array}{rl|ll}
12x^3 - 22x^2 + 16x - 15 & & 2x - 3 & \text{Divisor} \\
\underline{12x^3 - 18x^2 } & & \overline{6x^2 - 2x + 5} & \text{Quotient} \\
- 4x^2 + 16x - 15 & & & \\
\underline{- 4x^2 + 6x } & & & \\
10x - 15 & & & \\
\underline{10x - 15} & & &
\end{array}$$

Factoring is resolution of an algebraic expression into monomials, polynomials, or both, such that their product is the original expression. Procedure for removal of monomial factors is to determine by inspection the highest common factor of all terms and divide out at once. For polynomial factors the procedure is simple trial and error. Acquaintance with the following common forms is helpful.

$$(a + b)(x + y) = ax + ay + bx + by$$
$$(a + b)(a - b) = a^2 - b^2$$
$$(a + b)^2 = a^2 + 2ab + b^2$$
$$(a - b)^2 = a^2 - 2ab + b^2$$
$$(x + a)(x + b) = x^2 + (a + b)x + ab$$
$$(ax + b)(cx + d) = acx^2 + (ad + bc)x + bd$$
$$(a + b)(a^2 - ab + b^2) = a^3 + b^3$$
$$(a - b)(a^2 + ab + b^2) = a^3 - b^3$$

FRACTIONS

Important formulas.

$$\frac{a}{b} = \frac{na}{nb} = \frac{a \div n}{b \div n}; \quad +\frac{a}{b} = -\frac{-a}{b} = -\frac{a}{-b}; \quad \frac{a}{c} + \frac{b}{c} = \frac{a + b}{c}.$$

Rules. The value of a fraction is unchanged by multiplying numerator and denominator by same number, or by changing the sign of the fraction simultaneously with the sign of either numerator or denominator. Sum of fractions with a common denominator equals a fraction with the same denominator and with a numerator equal to the sum of the given numerators. A fraction is in its lowest terms when no factor except 1 is common to both numerator and denominator.

Addition and subtraction. Reduce each fraction to its lowest terms. Find least common denominator (L.C.D.). Reduce all fractions to a common denominator. Write resulting numerators as an algebraic sum over the common denominator. Combine numerator. Resolve resulting fraction to lowest terms.

Least common denominator = least common multiple (L.C.M.) of all denominators = that expression having the least number of factors which is divisible without remainder by each denominator. To obtain, resolve each denominator separately into its prime factors; the L.C.D. is the product of all different prime factors, each taken to the highest power at which it occurs in any denominator.

Example 1. Compute $s = \dfrac{4x^2 - 5}{3x^2} - \dfrac{2 - 3x}{2x} + \dfrac{3x - 7}{5x^3}$. Factors in denominators are $3 \cdot x \cdot x$; $2 \cdot x$; $5 \cdot x \cdot x \cdot x$. L.C.D. $= 3 \cdot 2 \cdot 5 \cdot x \cdot x \cdot x = 30x^3$. Multiply numerator and denominator (D) of each fraction separately by L.C.D./D, and set down with the original signs. Then

$$s = \frac{(4x^2 - 5)10x}{3x^2 \cdot 10x} - \frac{(2 - 3x)15x^2}{2x \cdot 15x^2} + \frac{(3x - 7)6}{5x^3 \cdot 6} = \frac{40x^3 - 50x - 30x^2 + 45x^3 + 18x - 42}{30x^3}$$
$$= \frac{85x^3 - 30x^2 - 32x - 42}{30x^3}.$$

Example 2. Compute $s = \dfrac{2}{x^2 - 7x} - \dfrac{3}{x} + \dfrac{3}{x - 7}$. L.C.D. $= x(x - 7)$ Hence $s = \dfrac{2}{x(x - 7)}$ $- \dfrac{3(x - 7)}{x(x - 7)} + \dfrac{3x}{x(x - 7)} = \dfrac{2 - 3(x - 7) + 3x}{x(x - 7)} = \dfrac{23}{x^2 - 7x}.$

Multiplication formula is $\frac{a}{b} \times \frac{c}{d} = \frac{ac}{bd}$. Numerators and denominators must be resolved into prime factors and the common factors in the products of numerators and of denominators canceled.

Division. Invert divisor, and proceed as in multiplication.

3. EQUATIONS

Definitions. An equation is a statement of equality between number symbols. An UNKNOWN is a symbol in an equation, the value of which is not known; it is found, if possible, by SOLVING THE EQUATION; when so solved, the value of the unknown, inserted in the original equation, makes the two sides demonstrably equal. LINEAR EQUATION (equation of first degree) is one in which the unknown, after clearing, is present only in the first degree. A QUADRATIC EQUATION (equation of second degree) is one which, after clearing, involves the square of the unknown but no higher power. LITERAL EQUATION is one in which knowns are expressed by letters as well as numerals.

General rules of manipulation. (1) The same quantity may be added to or subtracted from both sides of an equation without affecting the equality.

(2) Both sides of an equation may be multiplied or divided by the same quantity without affecting the equality.

(3) A term may be transposed from one side of an equation to the other, with simultaneous change of sign, without changing the equality.

(4) An equation containing fractions may be cleared by multiplying through (*i.e.*, multiplying both sides of the equation) by the L.C.M. of all of the denominators.

Rules for Solution of Equations

Linear equations of first degree. Transpose all terms containing unknown to left-hand side and all others to right-hand side. Combine left-hand terms into the form Ax, in which A combines all of the coefficients of x. Divide through by A.

Example. Solve: $7a + 4ax + \frac{3x}{b} = 2c - 4x - 8a + 2.$

Transpose: $4ax + \frac{3x}{b} + 4x = 2c - 8a + 2 - 7a$

Reduce: $x\left(4a + \frac{3}{b} + 4\right) = 2c - 15a + 2$

Divide through by coefficient of x: $x = (2c - 15a + 2)/\left(4a + \frac{3}{b} + 4\right)$.

Simultaneous linear equations. Two unknowns may be solved by (*a*) ADDITION and SUBTRACTION, or (*b*) SUBSTITUTION (see also Art. 4). Principle used is to ELIMINATE one unknown.

There is no solution when the equations are INCOMPATIBLE, as $x + 2y = 4$, and $x + 2y = 8$; there is an indeterminate number of solutions when the equations are DEPENDENT, as $x + 2y = 4$, and $2x + 4y = 8$, the second arising from the first by using the multiplier 2.

Example. Solve: (1) $5x - 3y = -1$, (2) $x + 2y = 5$.

(*a*) ***By addition and subtraction:*** Multiply (2) by 5:

Subtract: (1) $5x - 3y = -1$
(3) $5x + 10y = 25$

$-13y = -26. \quad \therefore y = 2.$

Substitute in (2): $x + 4 = 5. \quad \therefore x = 1.$

(*b*) ***By substitution:*** Solve (2) for x, giving $x = 5 - 2y$. Substitute in (1): $5(5 - 2y) - 3y = 1$. $\therefore -13y = -26.\ y = 2.$

Any number of unknowns in an equal number of **linear equations** may be solved in a similar manner by eliminating one variable from the system, thus reducing number of equations and number of variables by one, then another variable from the new system, etc.

Quadratic equations (SECOND DEGREE). Typical form is $ax^2 + bx + c = 0$. The equation has two solutions or ROOTS, x_1 and x_2.

Solution by formula.

$x_1 = (-b + \sqrt{b^2 - 4ac})/2a, \qquad x_2 = (-b - \sqrt{b^2 - 4ac})/2a.$

Sum of roots, $x_1 + x_2 = -b/a$.

Product of roots, $x_1x_2 = c/a$.

Solution of a quadratic equation may lead to roots which are IMAGINARY NUMBERS, involving the square root of a negative number, *e.g.*, $3 + \sqrt{-11}$. Numbers not imaginary are called REAL NUMBERS. The equation has EQUAL ROOTS when $b^2 - 4ac = 0$; IMAGINARY ROOTS when $b^2 - 4ac < 0$. (See p. 11.)

Solution by factoring. Many quadratic equations can be solved immediately by factoring to linear factors. Transpose all terms to the first member. Factor this, set each factor containing the unknown equal to zero, and solve the resulting equations.

A formula sometimes useful in factoring is

$$ax^2 + bx + c = a\left(x + \frac{b - \sqrt{b^2 - 4ac}}{2a}\right)\left(x + \frac{b + \sqrt{b^2 - 4ac}}{2a}\right).$$

Solution by completing the square. Transpose terms containing x to first member and other terms to second member. Divide both members by the coefficient of x^2. Add to both members the square of half the coefficient of x, thereby making the first member a perfect square. Rewrite the equation, expressing the first member as a square, and reduce the second member to its simplest form. Extract the square root of both members, writing the sign $\pm$ (plus and minus) before the square root of the second member, thus obtaining two linear equations.

Example. Solve $2x^2 - 9x + 4 = 0$. Successive steps give the equations, $2x^2 - 9x = -4$; $x^2 - 9/2\,x = -2$; $x^2 - 9/2\,x + (9/4)^2 = -2 + (9/4)^2$; $(x - 9/4)^2 = 49/16$; $\therefore x - 9/4 = \pm 7/4$. Hence, $x = 9/4 + 7/4 = 4$, and $x = 9/4 - 7/4 = 1/2$.

System involving a linear and a quadratic equation, two unknowns. Solve the linear equation for one unknown in terms of the other, substitute this value in the quadratic equation, and solve the resulting quadratic equation in one unknown. Substitute each root of this equation in the linear equation to find the corresponding value of the other unknown.

Graphical solution comprises plotting the equation or equations on paper suitably ruled and determining the points thereon that satisfy the specified conditions.

Plotting. Axes at right angles (Fig. 2) are $X'OX$, (X-AXIS) and $Y'OY$ (Y-AXIS). Construct a NUMBER SCALE on each line (equal divisions, each of equal numerical value), point O being marked zero on both. Distances parallel to X-axis are ABSCISSAE; they are positive when to the right of Y-axis, negative to the left. Distances parallel to Y-axis are ORDINATES, positive above the X-axis, negative below. The perpendicular distances from any point to the axes are the CO-ORDINATES of the point; their lengths, written in parenthesis, *e.g.*, (3, −4), abscissa first, define the point. Axes divide the plane into four QUADRANTS. Signs of co-ordinates for points in different quadrants are indicated in Fig. 2. Point O, co-ordinates (0, 0), is the ORIGIN.

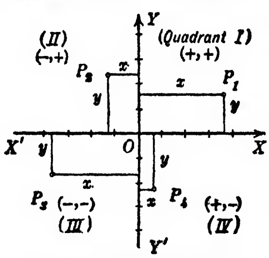

FIG. 2. Rectangular co-ordinates.

Graph of an equation in two unknowns. An indefinite number of corresponding pairs of values of x and y can be found to satisfy an equation; the line joining them is the GRAPH OF THE EQUATION. The graph of a linear equation is a straight line; that of all other equations is curved. To plot an equation in one unknown, *e.g.*, x, throw all terms onto one side and set them equal to another unknown, *e.g.*, y.

Simultaneous equations in two unknowns. The real-number solutions are the co-ordinates of the intersections of the two graphs.

Quadratic equation. (*a*) Plot y = quadratic. Real roots are abscissae of points at which the graph meets the X-axis. (Intersection with $y = 0$.) Graph of $ax^2 + bx + c = 0$ will cross, touch, or not meet the X-axis according as the roots are respectively real and unequal, equal, or imaginary. (*b*) Write the equation in the form $x^2 = ax + b$. Plot $y = x^2$, and $y = ax + b$. Abscissae of points of intersection are the required roots.

Equations of degree $n > 2$ in one unknown. (*a*) Transpose all terms to one side, set $= y$, and plot. The abscissa of each point of intersection with the X-axis is a real root (intersection with $y = 0$). (*b*) Transpose such terms to second member as may be desirable, plot y = first member, and y = second member. Abscissae of points of intersection of graphs are real roots.

Analytic solutions of higher-degree (>2) equations are numerous (5) and, in general, laborious. Several of the more useful follow.

Typical form of equation is

$$a_0x^n + a_1x^{n-1} + a_2x^{n-2} + \cdots a_{n-1}\,x + a_n = 0. \qquad \text{(A)}$$

Integral roots are found most readily by factoring, using the remainder theorem and the method of synthetic division. Every integral root of an equation with integral coefficients is a factor of the last term. By this theorem all possible integral roots are found in advance by factoring the last term.

Remainder theorem. When a polynomial in x is divided by $x - (r)$, the remainder obtained is the value of the polynomial resulting when r is substituted for x.

Example. When $3x^3 + 4x^2 - 6x + 5$ is actually divided by $x - 2$, the remainder is 33. For $x = 2$, $3\cdot 2^3 + 4\cdot 2^2 - 6\cdot 2 + 5 = 24 + 16 - 12 + 5 = 33$.

Synthetic division. To divide a polynomial in x by a linear factor of the form $x - (r)$, write down the successive coefficients a_0, a_1, a_2, etc., of descending powers of the polynomial in a horizontal line from left to right. Bring down the first coefficient a_0. Multiply a_0 by r and add the product to the second coefficient a_1. Multiply the sum $(a_0r + a_1)$ so obtained by r, and add to the third coefficient a_2. Continuing this process, the last sum will be the remainder, and the preceding sums from left to right the successive coefficients of descending powers of the quotient.

Example. The number $2(=r)$ is bracketed to the right of the line of coefficients. The first coefficient 3 is written down below the original ones. Multiply it by 2 and add the product $(3 \times 2 = 6)$ to the second coefficient 4. Multiply sum $(4 + 6 = 10)$ by 2, and add the product $(10 \times 2 = 20)$ to the third coefficient -6. Continuing, the last sum 33 is the remainder, and the preceding sums, 3, 10, and 14, are successive coefficients of the quotient $3x^2 + 10x + 14$.

Form. Divide $3x^3 + 4x^2 - 6x + 5$ by $x - 2$.

Solution
$$\begin{array}{l|l} 3 + \ \ 4 - \ \ 6 + \ \ 5 & 2 \\ \quad + \ \ 6 + 20 + 28 & \\ \hline \underbrace{3 + 10 + 14}\ (+33 = \textit{Remainder}) & \end{array}$$

Coefficients of quotient, $3x^2 + 10x + 14$.

If powers of x are missing in the given polynomial, their places must be supplied to zero coefficients. Thus to divide $x^3 + 8$ by $x + 2$, write $x^3 + 8 = x^3 + 0\cdot x^2 + 0\cdot x + 8$, and $x + 2 = x - (-2)$. Hence the work is
$$\begin{array}{l|l} 1 \quad 0 \quad 0 + 8 & -2 \\ \ \ - 2 + 4 - 8 & \\ \hline 1 - 2 + 4 \quad 0 & \end{array}$$

$\therefore\ x^3 + 8 = (x^2 - 2x + 4)(x + 2)$.

Synthetic division should be used to calculate the ordinates of a graph. Thus the graph of $3x^3 + 4x^2 - 6x + 5 = 0$ passes through (2, 33) the value 33 being found by synthetic division.

Number of linear factors and roots. An equation of degree n has precisely n linear factors of the form $x - r$, and, therefore, has n roots. A linear factor may be repeated. If $r_1, r_2, \ldots, r_n$ are roots of Eq. A (p. 10), it may be written

$$a_0(x - r_1)(x - r_2) \ldots (x - r_n) = 0. \qquad \text{(B)}$$

Relations between coefficients and roots. In an equation in which the coefficient of the highest power is unity, the coefficient of the second term with sign changed equals the sum of all the roots; the coefficient of the third term equals the sum of all products formed from two of the roots at a time; the coefficient of the fourth term with sign changed equals the sum of all the products formed from three of the roots at a time; etc. When the degree is even, the last coefficient equals the product of all roots; when odd, the last coefficient, with sign changed, equals the product of all roots.

Imaginary roots. If the imaginary number $a + b\sqrt{-1}$ (a and b being real numbers) is a root of an equation with real coefficients, $a - b\sqrt{-1}$ is a root also. Imaginary roots occur only in conjugate pairs in equations with real coefficients. The corresponding factors are $x - (a + b\sqrt{-1})$, and $x - (a - b\sqrt{-1})$. Their product is $x^2 - 2ax + a^2 + b^2$, and this product is a REAL QUADRATIC FACTOR of the equation.

Solution of numerical equation of higher degree by trial. Clear the equation of fractional coefficients. If one integral root can be found, a linear factor is known, and the quotient is quickly found by synthetic division. The remaining roots are roots of the equation obtained by setting the quotient equal to zero; an equation of degree less by one than original. Factor last term. Since $+1$ and -1 are always factors, each should be tried for a root (by inspection). If either is a root, remove corresponding factor $(x - 1)$ or $(x + 1)$. Other factors of last term should be tried by synthetic division. When enough factors have been removed to reduce the remaining quotient to a quadratic, this may be solved as usual.

Example. Solve $x^4 - x^3 - 9x^2 + 11x + 6 = 0$ by trial. Try $+1$ and -1. Substituting these values in turn, neither is a root. Other factors of 6 are ± 2, ± 3, ± 6. Trying $+2$, it turns out to be a root.

The equation now may be written

$$(x - 2)(x^3 + x^2 - 7x - 3) = 0.$$

The second factor shows that only $+3$ or -3 should be tried. Try -3. It is a root. Equation now is $(x - 2)(x + 3)(x^2 - 2x - 1) = 0$. Solving for roots of quadratic factor, they are found to be $1 \pm \sqrt{2}$. Hence the roots of the given equation are $2, -3, 1 + \sqrt{2}, 1 - \sqrt{2}$.

$$\begin{array}{l|l} 1 - 1 - 9 + 11 + 6 & 2 \\ \quad + 2 + 2 - 14 - 6 & \\ \hline 1 + 1 - 7 - \ \ 3 \quad 0 & \end{array}$$

$$\begin{array}{l|l} 1 + 1 - 7 - 3 & -3 \\ \ \ - 3 + 6 + 3 & \\ \hline 1 - 2 - 1 \quad 0 & \end{array}$$

Fractional roots. Equations of degree higher than two with no integral roots cannot be solved by the method just explained. Such equations may, however, have fractional roots. When the coefficient of the highest power is not 1, divide by it. The remaining coefficients may then be reduced to integers as follows. After dividing the equation by the coefficient of the highest power, write in any missing powers of x with zero coefficients. Insert factors m, m^2, m^3 . . . in second, third, fourth, . . . terms. Choose for m the smallest integer which will reduce all coefficients to integers. Roots of this transformed equation will be m-times the roots of the original equation. This transformation is called MULTIPLYING THE ROOTS BY m. Find integral roots of transformed equation by trial and divide each by the value of m. Quotients are roots of original equation.

Example. Solve $36x^4 - 55x^2 - 35x - 6 = 0$. Divide by 36, and write $x^4 + 0 \cdot x^3 - \frac{55x}{36} - \frac{35x}{36} - \frac{1}{6} = 0$. Putting in powers of m, $x^4 + 0 \cdot mx^3 - \frac{55}{36} m^2x^2 - \frac{35}{36} m^3x - \frac{1}{6} m^4 = 0$. Choose $m = 6$, giving $x^4 + 0 \cdot x^3 - 55x^2 - 210x - 216 = 0$. Roots of this equation are -2, -3, -4, 9.
Hence roots of original equation are $-1/3$, $-1/2$, $-2/3$, $3/2$. *Ans.*

All possible fractional roots may be found in this way because of the theorem: An equation in which the coefficient of the highest power is unity, and other coefficients integral, cannot have a fractional root.

Changing signs of roots. If the signs of alternate terms ($m = -1$) are changed, the transformed and original equations have roots differing only in sign.

Incommensurable roots. Real roots that are neither integral nor fractional may be computed to any number of decimal places by various methods. The existence of real roots is indicated by the LOCATION THEOREM: Substitute two real numbers a and b for x in the first member of the equation; if the resulting numerical values differ in sign, an odd number of roots will lie between $x = a$ and $x = b$. The graph of the equation must join points on opposite sides of the x-axis, hence must cross this axis an odd number of times. When a and b are successive integers, only one root will, as a rule, lie between them.

Example. In equation $x^3 - 6x^2 + 3x + 5 = 0$, putting $y =$ the first member, corresponding values of x and y are, by synthetic division:

x:	-1	0	1	2	5	6
y:	-5	5	3	-5	-5	23

One root lies between -1 and 0, one between 1 and 2, and one between 5 and 6. These roots are incommensurable, since there are no fractional nor integral roots.

Horner's method. Assume a positive root located between $x = h$ and $x = h + 1$, where h is an integer not zero. Substitute $x = y + h$ in the equation. Roots of this new equation in y will be roots of the original equation diminished by h. (Since $y = x - h$.) Hence the equation in y must have a root between 0 and 1. The first significant figure of this root (in first place of decimals) will be the second figure of the root of the original equation. If this root of the equation in y is located between $y = k$ and $y = k + 0.1$ (k being an integer in the tenth's place), put $y = z + k$. The equation in z will have a root between 0 and 0.1, and its first significant figure in the hundredth's place will be the third figure of the root sought of the equation in x. This outline of HORNER'S METHOD FOR POSITIVE ROOTS indicates that a suite of equations (A), (B), (C), . . . is obtained by transformations which diminish the roots by a given number.

Example. Diminish the roots of $x^3 - 6x^2 + 3x + 5 = 0$ by 1.

$$\begin{array}{l}
1 - 6 + 3 + 5 \;\underline{|1} \\
\underline{\quad + 1 - 5 - 2} \\
1 - 5 - 2(+3) = \text{1st remainder} \\
\underline{\quad + 1 - 4} \\
1 - 4(-6) = \text{2nd remainder} \\
\underline{\quad + 1} \\
1(-3) = \text{3rd remainder}
\end{array}$$

The transformed equation is $x^3 - 3x^2 - 6x + 3 = 0$. (The example shows compact arrangement of the work by synthetic division.)

To diminish the roots of an equation by any given number h. Divide the given equation by $x - h$. The remainder is the last coefficient in the transformed equation. Divide the quotient obtained by $x - h$. The remainder is the coefficient of the next to last term in the transformed equation. Continue this process, the last remainder being the coefficient of the second term in the new equation. The coefficients of the highest powers are the same in the original and transformed equations.

Negative roots. Write down an equation with roots differing only in sign from those of the given equation (above), and calculate the positive roots of this equation. In locating roots greater than 10 and less than 100, it suffices to use the intervals 10, 20, 30, etc. To avoid diminishing by a number greater than 10, multiply roots by 0.1 (above).

In the transformed equation, the root desired will lie between successive integers. For a root greater than 100, multiply roots by 0.01. In reduction by a figure in the tenth's place, decimals can be avoided by first multiplying roots by 10; similarly for a figure in any succeeding place. Diminishing by a figure in unit's place establishes the sign of the first remainder (constant term), which must remain unchanged in the succeeding equations. The correct figure in a decimal place (not tenth's place) may usually be found by rejecting all but the last two terms of the equation, the assumption being that the value of the terms rejected will not affect the result. Caution must be observed in doing this, however. At a certain stage more than one figure can be found by dividing the last by the preceding coefficient (with sign changed).

Example. Calculate the root of $x^3 - 6x^2 + 3x + 5 = 0$ lying between 1 and 2. *Solution.* Diminish the roots by 1. New equation is $x^3 - 3x^2 - 6x + 3 = 0$. This equation has a root between 0.4 and 0.5. Diminish the roots by 0.4.

$$\begin{array}{llll} 1 & -\,3.0 & -\,6.00 & +\,3.000 \;\underline{|\,0.4} \\ & \underline{+\,0.4} & \underline{-\,1.04} & \underline{-\,2.816} \\ 1 & -\,2.6 & -\,7.04(+\,0.184) & \\ & \underline{+\,0.4} & \underline{-\,0.88} & \\ 1 & -\,2.2(-\,7.92) & & \\ & \underline{+\,0.4} & & \\ 1(-\,1.8) & & & \end{array}$$

The transformed equation is $x^3 - 1.8x^2 - 7.92x + 0.184 = 0$. It has a root between 0 and 0.1. Neglecting the two first terms, $-7.92x + 0.184 = 0$, $x = 0.02$. Diminish by 0.02. Transformed equation is $x^3 - 1.74x^2 - 7.9908x + 0.024888 = 0$. The root of this equation between 0 and 0.01 is $x = \dfrac{0.024888}{7.9908} = 0.003$. Hence root is 1.423 to three places.

The last division may be carried farther. $x = 0.024888 \div 7.9908 = 0.00311$. Value of rejected terms $(x^3 - 1.74x^2)$ for x between 0.003 and 0.004 lies between -0.000015 and -0.000028, therefore three figures may be found by division. The root is 1.42311 to 5 places.

Number of real roots. When two consecutive coefficients in an equation have like signs a PERMANENCE OF SIGN is said to occur, if unlike signs, a VARIATION OF SIGN occurs. DESCARTES' RULE OF SIGNS states that the number of positive roots cannot exceed the number of variations of sign, nor can the number of negative roots exceed the number of permanences of sign. Existence of imaginary roots may often be established by this rule.

Example. In $x^3 + 5x + 7 = 0$, no variation of sign occurs; therefore there is no positive root. Writing in x^2 with coefficient -0, signs are $+-++$, only one permanence, hence not more than one negative root. Equation has one real root which is negative and a pair of conjugate imaginary roots.

Sturm's theorem gives a method of determining the number of real roots between two numbers $x = a$, $x = b$. (5)

Solution of cubic equation, $x^3 + 3Hx + G = 0$

Graphical solution. Plot $y = x^3$, and $y = -3Hx - G$. Abscissae of points of intersection are roots.

Formula. Put $J = G^2 + 4H^3$.

Case I. J positive. One root only is real, $x = \sqrt[3]{-\tfrac{1}{2}G + \sqrt{J}} + \sqrt[3]{-\tfrac{1}{2}G - \sqrt{J}}$.

Case II. $J = 0$. All roots are real and two equal $x_1 = 2\sqrt[3]{-\tfrac{1}{2}G} = x_2$.

Case III. J negative. Roots all real and distinct. Determine the angle t between 0° and 180° for which $\cos t = -G/2H\sqrt{-H}$. Roots are $x_1 = 2\sqrt{-H}\cos \tfrac{1}{3}t$, $x_2 = 2\sqrt{-H}\cos(\tfrac{1}{3}t + 120°)$, $x_3 = 2\sqrt{-H}\cos(\tfrac{1}{3}t + 240°)$.

To eliminate x^2 from $ax^3 + bx^2 + cx + d = 0$, put $z = ax + \tfrac{1}{3}b$, or $x = (3z - b)/3a$.

4. DETERMINANTS

Formulas for solving linear systems can be written down in compact form by use of determinants, which are arrangements of numbers in the form of squares. (5)

Second order. $\begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix} = a_1b_2 - a_2b_1.$

Third order. $\begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} = a_1 \begin{vmatrix} b_2 & c_2 \\ b_3 & c_3 \end{vmatrix} - a_2 \begin{vmatrix} b_1 & c_1 \\ b_3 & c_3 \end{vmatrix} + a_3 \begin{vmatrix} b_1 & c_1 \\ b_2 & c_2 \end{vmatrix}.$

$$= a_1b_2c_3 - a_1b_3c_2 - a_2b_1c_3 + a_2b_3c_1 + a_3b_1c_2 - a_3b_2c_1.$$

Fourth order.

$$\begin{vmatrix} a_1 & b_1 & c_1 & d_1 \\ a_2 & b_2 & c_2 & d_2 \\ a_3 & b_3 & c_3 & d_3 \\ a_4 & b_4 & c_4 & d_4 \end{vmatrix} = a_1 \begin{vmatrix} b_2 & c_2 & d_2 \\ b_3 & c_3 & d_3 \\ b_4 & c_4 & d_4 \end{vmatrix} - a_2 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_3 & c_3 & d_3 \\ b_4 & c_4 & d_4 \end{vmatrix} + a_3 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_2 & c_2 & d_2 \\ b_4 & c_4 & d_4 \end{vmatrix} - a_4 \begin{vmatrix} b_1 & c_1 & d_1 \\ b_2 & c_2 & d_2 \\ b_3 & c_3 & d_3 \end{vmatrix}.$$

The numbers are called ELEMENTS. If the row and column in which an element lies are erased, the determinant remaining is called the CORRESPONDING MINOR of that element. The value of a determinant is expressed as a sum of products of successive elements of a row (or column) by corresponding minors with alternating signs, as shown above for the elements of the first column.

Solution of linear systems

Two unknowns. $a_1x + b_1y = c_1$, $a_2x + b_2y = c_2$.

$$x = \begin{vmatrix} c_1 & b_1 \\ c_2 & b_2 \end{vmatrix} \div \begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}, \quad y = \begin{vmatrix} a_1 & c_1 \\ a_2 & c_2 \end{vmatrix} \div \begin{vmatrix} a_1 & b_1 \\ a_2 & b_2 \end{vmatrix}.$$

Three unknowns. $a_1x + b_1y + c_1z = d_1$, $a_2x + b_2y + c_2z = d_2$, $a_3x + b_3y + c_3z = d_3$.

$$D = \begin{vmatrix} a_1 & b_1 & c_1 \\ a_2 & b_2 & c_2 \\ a_3 & b_3 & c_3 \end{vmatrix} \neq 0. \quad x = \frac{\begin{vmatrix} d_1 & b_1 & c_1 \\ d_2 & b_2 & c_2 \\ d_3 & b_3 & c_3 \end{vmatrix}}{D}, \quad y = \frac{\begin{vmatrix} a_1 & d_1 & c_1 \\ a_2 & d_2 & c_2 \\ a_3 & d_3 & c_3 \end{vmatrix}}{D}, \quad z = \frac{\begin{vmatrix} a_1 & b_1 & d_1 \\ a_2 & b_2 & d_2 \\ a_3 & b_3 & d_3 \end{vmatrix}}{D}.$$

Similar formulas hold for any number of unknowns.

Properties of determinants. (1) Interchanging the corresponding elements of two columns (or rows) changes the sign of the determinant. (2) If corresponding elements of two rows (or columns) are identical, the determinant is zero. (3) Columns may be changed to rows and rows to columns. (4) If all the elements of a column are multiplied by a number m, the value of the determinant is multiplied by m. (5) The value of a determinant is unchanged, if the elements of a column are multiplied by m and added to corresponding elements of any other column.

5. EXPONENTS

Exponents. For any numbers m, n, the following formulas hold: $a^m \times a^n = a^{m+n}$; $a^m/a^n = a^{m-n}$; $(a^m)^n = a^{mn}$; $a^0 = 1$, $1/a^n = a^{-n}$; $a^m b^m = (ab)^m$; $a^{\frac{1}{r}} = \sqrt[r]{a}$; $\sqrt[r]{a} \times \sqrt[r]{b} = \sqrt[r]{ab}$ (r a positive integer).

Radicals. A radical is an indicated root of an algebraic or arithmetic expression. Operations with radicals are performed by changing to exponents. $\sqrt[r]{A} = A^{1/r}$.

Example. $\sqrt{2} \times \sqrt[3]{3} = 2^{1/2} \times 3^{1/3} = 2^{3/6} \times 3^{2/6} = (2^3)^{1/6} \times (3^2)^{1/6} = 8^{1/6} \times 9^{1/6} = (72)^{1/6} = \sqrt[6]{72}$. *Ans.*

Division by radicals may be avoided by RATIONALIZING.

Example. To compute $\dfrac{\sqrt{3} + \sqrt{2}}{\sqrt{5} - \sqrt{3}}$, multiply numerator and denominator by $\sqrt{5} + \sqrt{3}$. This rationalizes the denominator, for $(\sqrt{5} - \sqrt{3})(\sqrt{5} + \sqrt{3}) = 5 - 3 = 2$, hence the value $1/2\,(\sqrt{3} + \sqrt{2})(\sqrt{5} + \sqrt{3}) = 1/2\,(3 + \sqrt{6} + \sqrt{10} + \sqrt{15})$.

6. CHANCE

Permutation of any number of things is a group of some or all of them, arranged in a definite order (5). The number of permutations of m different things taken r at a time is the product of successive decreasing integers from m down to $m - r + 1$. The number of permutations of m different things taken all together is the product of all integers from 1 to m. The product $1 \cdot 2 \cdot 3 \cdot \ldots \cdot m$ is called FACTORIAL m, and written $m!$. The formula for the number of permutations of m things r at a time is $m!/(m - r)!$.

Combination of any number of things is a group of some or all of them, without reference to order in the group. The number of combinations of m different things r at a time

equals the number of permutations divided by factorial r, namely $m!/(m-r)!\,r!$. Given two groups of m and n things respectively, the number of selections (combinations) of $r+s$ things, r from first group and s from second group equals $m!\,n!/(m-r)!\,(n-s)!\,r!\,s!$.

Probability that an event will happen is the ratio of the number of favorable cases to the whole number of cases that can occur. (6)

Example. From an urn containing 5 black and 4 white balls, 3 balls are drawn at random. What is the probability that 2 will be black and 1 white?

From 9 balls 3 may be drawn in $9 \times 8 \times 7/3! = 84$ ways. (This is the number of combinations of 9 things 3 at a time.) The number of favorable cases (formula above) is $5!\,4!/3!\,3!\,2! = 40$. Hence the required probability is $40/84 = 10/21$, *i.e.*, 10 chances in 21.

If the probabilities of two events are a and b, respectively, the probability of simultaneous occurrence is ab, and of occurrence of one or the other is $a+b$.

Example. The probability of drawing a knave from a full pack of cards is 1/13. The probability of drawing a spade is 1/4. Hence the probability of drawing the knave of spades is $1/13 \cdot 1/4 = 1/52$. Probability of drawing a knave or an ace is $1/13 + 1/13 = 2/13$.

7. PROGRESSIONS

Arithmetic progression is a sequence of terms each of which differs from the preceding by the same number d (COMMON DIFFERENCE). If n = number of terms, a = first term, l = last term, s = sum of n terms, then $l = a + (n-1)d$, and $s = \frac{n}{2}(a+l)$. ARITHMETIC MEAN of two numbers is half their sum.

Geometric progression is a sequence of terms each of which is obtained from the preceding by multiplying it by a fixed number r (RATIO). If n = number of terms, a = first term, l = last term, s = sum of n terms, then $l = ar^{n-1}$, $s = (rl-a)/(r-l)$. GEOMETRIC MEAN of two numbers m, n is $\sqrt{mn}$.

8. BINOMIAL THEOREM

The binomial theorem is a formula for expanding a power of the sum of two terms.

$$(a+b)^n = a^n + na^{n-1}b + \frac{n(n-1)}{1\cdot 2}a^{n-2}b^2 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}a^{n-3}b^3 + \cdots$$

If n is a positive integer, the right-hand member contains $n+1$ terms and the last term is b^n. The product of the coefficient in any term and the exponent of a in that term divided by the exponent of b increased by 1 gives the coefficient of the next term. If n is not a positive integer, the sequence of terms of the second member does not terminate but leads to an INFINITE SERIES. The formula holds then only when $|b| < |a|$. (See under Series, Art. 22.)

Table 2. Binomial coefficients

r	$\binom{r}{2}$	$\binom{r}{3}$	$\binom{r}{4}$	$\binom{r}{5}$
0.1	−0.0450	0.0285	−0.0207	0.0161
0.2	−0.0800	0.0480	−0.0336	0.0255
0.3	−0.1050	0.0595	−0.0402	0.0297
0.4	−0.1200	0.0640	−0.0416	0.0300
0.5	−0.1250	0.0625	−0.0391	0.0273
0.6	−0.1200	0.0560	−0.0336	0.0228
0.7	−0.1050	0.0455	−0.0262	0.0173
0.8	−0.0800	0.0320	−0.0176	0.0113
0.9	−0.0450	0.0165	−0.0087	0.0054

Coefficients 1, n, $\frac{n(n-1)}{1\cdot 2}$, $\frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}$, $\frac{n(n-1)(n-2)(n-3)}{4!}$, etc., are called BINOMIAL COEFFICIENTS. A convenient notation is $n = \binom{n}{1}$, $\frac{n(n-1)}{1\cdot 2} = \binom{n}{2}$, $\frac{n(n-1)(n-2)}{1\cdot 2\cdot 3} = \binom{n}{3}$, etc. When n = a positive integer, the rth coefficient from the beginning and the rth from the last are equal. (See Table 2.)

9. INTERPOLATION

Series of differences. From a given sequence a_1, a_2, a_3, a_4, etc., form the sequence of FIRST DIFFERENCES $a_2 - a_1$, $a_3 - a_2$, etc., obtained by subtracting each term from the preceding term. From this sequence a third series of SECOND DIFFERENCES may be formed, and so on.

Let b_1, b_2, b_3, etc., be the series of first differences;
c_1, c_2, c_3, etc., be the series of second differences;
d_1, d_2, d_3, etc., be the series of third differences.

The formula for $(n+1)$th term of original sequence is $a_{n+1} = a_1 + nb_1 + \frac{n(n-1)}{1\cdot 2}c_1 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}d_1 + \ldots$ Formula for sum s of n terms is,

$$s = na_1 + \frac{n(n-1)}{1\cdot 2}b_1 + \frac{n(n-1)(n-2)}{1\cdot 2\cdot 3}c_1 + \ldots$$

Application of the formula is to cases when differences of a certain order all vanish. In an arithmetic progression, for example, second-order differences are zero.

Example. Find the sum of 11 terms of the series 1, 5, 12, 24, 43, 71, etc.
Solution. $a_1 = 1$, $b_1 = 4$, $c_1 = 3$, $d_1 = 2$, $n = 11$.
$s = 11 + 220 + 495 + 660 = 1386$. *Ans.*

```
1   5   12   24   43   71
  4   7   12   19   28
    3   5    7    9
      2   2    2
        0    0
```

Sums of powers of integers 1, 2, 3, . . . n.
Sum of first powers $= \frac{1}{2}n(n+1)$.
Sum of second powers $= \frac{1}{6}n(n+1)(2n+1)$.
Sum of third powers $= (\frac{1}{2}n(n+1))^2$.

Interpolation by differences of higher order. A numerical table usually gives values $y_1, y_2, y_3, \ldots$ of a function y corresponding to values $x_1, x_2, x_3, \ldots$ of x. Successive values of x differ by a constant difference d (form an arithmetic progression). From the values of y, form a series of differences of the first order, second order, etc., and let D_1, D_2, etc., be the first terms, respectively, of these series. To interpolate a value of y, say y', corresponding to the value $x' = x_1 + rd (d = x_2 - x_1, r < 1)$ of x between x_1 and x_2, use INTERPOLATION FORMULA,

$$y' = y_1 + rD_1 + \frac{r(r-1)}{1\cdot 2}D_2 + \frac{r(r-1)(r-2)}{1\cdot 2\cdot 3}D_3 + \ldots$$

Differences above a certain order are assumed very small.

If differences above the first order are negligible, the formula $(y' = y' + rD_1)$ becomes the usual proportion $(y' - y_1) : (x' - x_1) = (y_2 - y_1) : (x_2 - x_1)$, for INTERPOLATION BY FIRST DIFFERENCES.
In using the above formula attention should be paid to the remarks under ***Fundamental arithmetic calculations*** (Art. 1).

10. COMPLEX NUMBERS

If a and b are real numbers, $a + b\sqrt{-1}$ is a COMPLEX NUMBER. Write $i = \sqrt{-1}$, $i^2 = -1$. Number i is called IMAGINARY UNIT. When $a = 0$, the complex number is a pure imaginary, or simply imaginary, number. Complex numbers differing only in the sign of the imaginary part are said to be CONJUGATE. Point with coordinates (a, b) represents $a + bi$ graphically (Fig. 3). Real numbers are represented by points on X-axis (number scale), imaginary numbers by points on Y-axis. Formal laws of operation in algebra apply to complex numbers, remembering always that $i^2 = -1$. This representation of complex numbers is a counterpart of a number scale for real numbers.

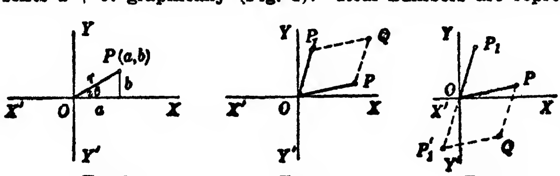

FIG. 3. FIG. 4. FIG. 5.
Graphs of complex numbers.

Addition. The sum of $a + bi$ and $a_1 + b_1 i$ is $(a + a_1) + (b + b_1)i$. To construct graphically point Q corresponding to the sum of numbers, represented by P and P_1, draw parallelogram $OPQP_1$ (Fig. 4). Regarding OP and OP_1 as vectors, the operation of addition is VECTOR ADDITION.

Subtraction. Difference of $a + bi$ and $a_1 + b_1 i$ is $(a - a_1) + (b - b_1)i$. To construct corresponding point Q, plot $P_1'(-a_1, -b_1)$, and draw parallelogram $OPQP_1'$ (Fig. 5).

Absolute value and amplitude of $a + bi$ are respectively the polar coordinates r and θ (p. 33) of $P(a, b)$ (Fig. 3).

$$r = +\sqrt{a^2 + b^2} = |a + bi| \qquad a = r\cos\theta \qquad b = r\sin\theta.$$

Hence $a + bi = r(\cos\theta + i\sin\theta)$.
Absolute value r is also called MODULUS, and amplitude θ ANGLE OF ARGUMENT. The amplitude given by $a = r\cos\theta$, $b = r\sin\theta$ is a unique angle less than 360°.

Multiplication of $a + bi$ and $a_1 + b_1i$. Write in polar form $a + bi = r(\cos\theta + i\sin\theta)$, $a_1 + b_1i = r_1(\cos\theta_1 + i\sin\theta_1)$. Then $(a + bi)(a_1 + b_1i) = rr_1[\cos(\theta + \theta_1) + i\sin(\theta + \theta_1)]$. The absolute value of the product of two complex numbers is the product of the absolute values, and the amplitude is the sum of the amplitudes. Multiplication by i has the effect of rotating a point through 90°, by $i^2 = -1$ through 180°, by $i^3 = -i$, through 270°.

Division of two complex numbers $a + bi$ and $c + di$ is worked as follows:

$$\frac{a + bi}{c + di} = \frac{a + bi}{c + di} \times \frac{c - di}{c - di} = \frac{ac + bd + (bc - ad)i}{c^2 + d^2}.$$

Absolute value of the quotient of two complex numbers is the quotient of the absolute values of numerator and denominator, and the amplitude of the quotient is the difference of the amplitudes of numerator and denominator.

Powers and roots. For a positive integer n, $(a + bi)^n = r^n(\cos\theta + i\sin\theta)^n = r^n(\cos n\theta + i\sin n\theta)$. When $r = 1$, this is known as DEMOIVRE'S THEOREM.

$$\sqrt[n]{a + bi} = \sqrt[n]{r}\,(\cos\theta + i\sin\theta)^{\frac{1}{n}} = \sqrt[n]{r}\,(\cos\theta/n + i\sin\theta/n).$$

In this formula, θ has n values differing by 360°, namely, θ_1 (amplitude of $a + bi < 360°$), $\theta_1 + 360°$, $\theta_1 + 720°$, . . ., $\theta_1 + (n - 1)\,360°$. The nth root of a real number has n distinct values, one real, the others complex.

Cube roots of unity are found by setting $n = 3$, $r = 1$, $\theta = 0$, 360°, 720°. They are 1, $\cos 120° + i\sin 120°$, $\cos 240° + i\sin 240°$, that is, $1, -1/2 + \sqrt{-3/2}, -1/2 - \sqrt{-3/2}$. Points representing these roots are the vertices of an equilateral triangle inscribed in a circle drawn with unit radius about the origin, one vertex being (1, 0). Similarly, the vertices of a regular polygon of n sides inscribed in this circle, one vertex (1, 0), will represent the nth roots of unity.

Exponentials, trigonometric functions, and complex numbers. The relations are

$$e^{ix} = \cos x + i\sin x,$$
$$\sin x = (e^{ix} - e^{-ix})/2i;$$
$$\cos x = (e^{ix} + e^{-ix})/2.$$

From these relations, $e^{2\pi i} = 1$; $e^{\pi i} = \cos\pi + i\sin\pi = -1$; $e^{\pi i/2} = i$; $e^{\pi i/4} = +\sqrt{i} = \cos\pi/4 + i\sin\pi/4$.

Logarithm of a complex number $a + bi = re^{i\theta}$ is a complex number, $\log r + i\theta$. Since θ may be replaced by $\theta + 2n\pi$ (n any integer), $\log(a + bi) = \log r + i(\theta + 2\pi n)$. Points representing log $(a + bi)$ lie on a line parallel to Y-axis, to the right a distance equal to $\log r$.

11. PRECISION OF MEASUREMENTS

Arithmetic mean. If a number of measurements are made to determine directly the unknown magnitude of a certain object, all measurements being made with equal skill and care, the MOST PROBABLE VALUE of the unknown is the arithmetical mean of all the measurements. That is, with n measurements $x_1, x_2, x_3 \ldots x_n$, the most probable value x_0 is $x_0 = (x_1 + x_2 + x_3 + \ldots + x_n)/n$. (6)

The basis for this assumption is that, on the average, errors in excess (POSITIVE ERRORS) and errors in defect (NEGATIVE ERRORS) are evenly balanced, so that the sum of the errors is zero.

Least squares. If the unknown magnitude is x, it can be readily shown by calculus (Art. 21) that the most probable value is that for which the sum of the squares of the errors, *i.e.*, $(x_1 - x)^2 + (x_2 - x)^2 + \ldots + (x_n - x)^2$ is a minimum.

Weighted measurements. If the method of making measurements shows that weights w_1, w_2, etc., should be assigned to measurements x_1, x_2, etc., then the most probable value of the unknown is the WEIGHTED MEAN, $x_0 = (w_1x_1 + w_2x_2 + \ldots + w_nx_n)/(w_1 + w_2 + \ldots + w_n)$.

Residuals are differences $x_1 - x_0$, $x_2 - x_0$, etc., between the observed values and the most probable value, and are denoted by v_1, v_2, etc. Evidently $v_1 + v_2 + \ldots + v_n = 0$.

Probable error of an observation is a number such that the actual error of that observation may with equal chances be greater or less than the probable error. For example, if a measurement is 30.726 with a probable error of ±0.014, the meaning is that the correct value is just as likely to lie between 30.712 and 30.740 as outside these limits. The probable error gives a measure of the precision of a measurement. Weights to be attached to different determinations of the same quantity are inversely proportional to the squares of the probable errors. Formulas for computing probable error follow. Numerical values of residuals are $|v_1|$, $|v_2|$, etc., number of observations is n.

Probable error (r) **of single observation,**

$$r = \frac{0.6745}{\sqrt{n - 1}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}. \qquad \text{(STANDARD FORMULA)}$$

$$r = \frac{0.8453}{\sqrt{n(n - 1)}}(|v_1| + |v_2| + \ldots |v_n|).$$

(PETER'S FORMULA, approximate)

Probable error (r_0) **of arithmetical mean,**

$$r_0 = r/\sqrt{n}; \quad r_0 = \frac{0.6745}{\sqrt{n(n-1)}}\sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}.$$

(STANDARD FORMULA)

$$r_0 = \frac{0.8453}{n\sqrt{n-1}}(|v_1| + |v_2| + \ldots + |v_n|).$$

(PETER'S FORMULA, approximate)

For tables of values of coefficient of parentheses, see (6).

Example. The following are ten measurements M of the length of a base line. Below are given the values of residuals, v, and the squares of residuals.

M: 455.35, 455.35, 455.20, 455.05, 455.75, 455.40, 455.10, 455.30, 455.50, 455.30.

M_0 = arithmetic mean = 455.330.

v: 0.02, 0.02, −0.13, −0.28, 0.42, 0.07, −0.23, −0.03, 0.17, −0.03.

v^2: 0.0004, 0.0004, 0.0169, 0.0784, 0.1764, 0.0049, 0.0529, 0.0009, 0.0289, 0.0009.

Hence $v_1^2 + v_2^2 + \ldots + v_n^2 = 0.3610$. And $|v_1| + |v_2| + \ldots + |v_n| = 1.40$.

$\therefore$ by the standard formulas, $r = \frac{0.6745}{\sqrt{9}}\sqrt{0.3610} = 0.13$, $r_0 = r/\sqrt{10} = 0.042$.

By the approximate formulas, $r = \frac{0.8453}{\sqrt{90}}(1.40) = 0.12$. $r_0 = 0.039$.

For the most probable length of the base line, the result is 455.330 with probable error ±0.042 (using result given by standard formula), usually written 455.330 ± 0.042. Note also that five of the residuals are numerically less than the probable error of a single observation. In fact, in any considerable number of observations it should be the case that half of the residuals are less than the probable error

Probable error of a function of a single measured quantity equals the product of the derivative of the function (Art. 20) by the probable error of the measured quantity.

Test of precision. To test a given set of measurements of an unknown quantity, make use of the normal distribution of residuals for the purpose of obtaining a comparison of the data of the experiment with results established by theory and confirmed by practice. By Table 3, the normal number of residuals ($= y$) numerically less than an assumed value ($= a$) for n measurements can be written down; the probable error of a single observation is r (see p. 17).

Table 3. Normal distribution of residuals; values of ratio y/n

a/r	0.0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9
0	0.000	0.054	0.107	0.160	0.213	0.264	0.314	0.363	0.4105	0.456
1	0.500	0.542	0.582	0.619	0.655	0.688	0.7195	0.7485	0.775	0.800
2	0.823	0.843	0.862	0.879	0.8945	0.908	0.9205	0.931	0.941	0.9495
3	0.957	0.9635	0.969	0.974	0.978	0.982	0.985	0.987	0.990	0.9915
4	0.993	0.994	0.995	0.996	0.997	0.998	0.998	0.9985	0.9988	0.999
5	0.999	....	....	....	....	....	....	....	....	....
∞	1.000	....	....	....	....	....	....	....	....	....

a	a/r	y	Y	Actual
0.00	0.00	0.00	......	......
0.05	0.37	7.84	8	9
0.10	0.74	15.2	7	6
0.20	1.5	27.5	12	12
0.30	2.2	34.5	7	8
0.40	2.9	38	4	3
∞	∞	40	2	2

Example. In an experiment 40 measurements were made and the probable error of a single observation was $r = 0.136$. For $a = 0.05$, $a/r = 0.37$. The above table gives $y/n = 0.196$. Hence $y = 7.84$, that is, there should be normally 8 residuals not exceeding 0.05 in numerical value. Values of y are tabulated corresponding to assumed values of a, and under Y is written down the normal distribution of residuals for the experiment, namely, 8 residuals not exceeding 0.05, 7 residuals numerically between 0.05 and 0.10, inclusive, etc. Actual numbers of residuals are given in the last column; comparison shows a satisfactory result.

Rejection of measurements. To test for rejection, calculate y/n by the formula $y/n = (2n-1)/2n$, and from the above table find a/r, and then a. This value of a gives a maximum numerical value for all residuals, and any measurement in which the residual exceeds this value should be rejected.

Example. In the experiment above, $n = 40$, and $y/n = (80-1)/80 = 0.987$. Hence $a/r = 3.7$, and $a = 3.7 \times 0.136 = 0.50$. No residual should exceed 0.50 in numerical value. Maximum residual in the experiment was 0.45.

Constant errors due to some fixed cause such as conditions under which the experiment was made, defects in instruments, personal peculiarity of observer, etc., are supposed to have been detected and eliminated before the methods explained above are applied.

Solution of a system of linear equations by least squares. The problem of determining the empirical law satisfied by given data (Art. 25) involves the solution of a system of linear equations in which the number of equations exceeds the number of unknowns. For such a system the question is the most probable values of the unknowns. The method of solution of a system with three unknowns x, y, z illustrates the general method. (6)

Example. The data of the experiment establish a system of n OBSERVATION EQUATIONS with unknowns x, y, z. Form a system of NORMAL EQUATIONS equal in number to the number of unknowns as follows: (1) Multiply each observation equation by the coefficient of x in that equation, and add the resulting equations. This gives the first normal equation in which $a_1^2 + a_2^2 + \ldots + a_n^2 = [aa]$; $a_1b_1 + a_2b_2 + \ldots + a_nb_n = [ab]$, etc., adopting a convenient notation. (2) Multiply each observation equation by the coefficient of y in that equation, and add the resulting equations. This gives the second normal equation. (3) Multiply each observation equation by the coefficient of z in that equation, and add the resulting equations. This gives the third and, in this example, last normal equation. (4) Solve the normal equations for x, y, z. For these values, x', y', z', the sum of the squares of the left-hand members of the observation equations, will be less than for any other values of x, y, z.

$$\begin{array}{c} a_1x + b_1y + c_1z + d_1 = 0 \\ a_2x + b_2y + c_2z + d_2 = 0 \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ \cdot \quad \cdot \quad \cdot \quad \cdot \\ a_nx + b_ny + c_nz + d_n = 0 \end{array}$$

Normal equations

$$\begin{array}{l} [aa]x + [ab]y + [ac]z + [ad] = 0 \\ [ba]x + [bb]y + [bc]z + [bd] = 0 \\ [ca]x + [cb]y + [cc]z + [cd] = 0 \end{array}$$

The problem is to be regarded as one in which n observations are made upon the linear function $ax + by + cz + d$ of x, y, z, each observation establishing a set of values of a, b, c, d. The probable error r of a single observation is given by

$$r = \frac{0.6745}{\sqrt{n-q}} \sqrt{v_1^2 + v_2^2 + \ldots + v_n^2}, \text{ (standard formula)}$$

or

$$r = \frac{0.8453}{\sqrt{n(n-q)}} (|v_1| + |v_2| + \ldots + |v_n|), \text{ (approximate formula)}$$

where

$$q = \text{the number of unknowns, } v_1 = a_1x' + b_1y' + c_1z' + d_1$$

$$v_2 = a_2x' + b_2y' + c_2z' + d_2, \text{ etc.}$$

12. INTEREST AND ANNUITIES

Compound interest. Let P = principal, i = interest on one dollar per year, n = number of years, A = amount after n years. Then $A = P(1 + i)^n$, when interest is compounded annually.

$A = P(1 + i/t)^{nt}$, when interest is compounded t times per year. From the first formula, $P = A/(1 + i)^n$, which gives the principal when the other quantities are known; $n = (\log A - \log P)/\log (1 + i)$, giving time.

Table 30, Sec. 22, gives values of A when $P = 1$, $t = 1$, that is, gives values of A computed by the formula $A = (1 + i)^n$. This table can be used also when interest is compounded more often than once a year by taking i/t as percentage rate, and nt as number of years. For example, if interest is compounded semi-annually, halve the rate and double the time. To find amount, multiply the number in the table by the principal. Table 31, Sec. 22, gives the principal which will amount to (present value of) one dollar in a given time at a given rate when interest is compounded annually, that is, is computed from $P = 1/(1 + i)^n$. For interest periods less than one year, proceed as above. To find the present value of any sum (discount any sum), multiply tabular number by this sum. (7)

Annuity. An annuity is a series of equal payments made at equal periods of time, the first payment being made at the end of the first period. Let R = payment, i = interest on one dollar per year, n = number of years during which payments are continued, A = amount of annuity after n years, P = present value; then $A = R[(1 + i)^n - 1]/i$, when payments are made annually and interest is compounded annually.

Table 32, Sec. 22, gives the amount of an annuity of one dollar for various rates and periods. For the amount of an annuity of any sum, multiply the tabular number by the sum. Formula for present value is $P = R(1 - (1 + i)^{-n})/i$. Table 33, Sec. 22, gives the present value of an annuity of one dollar extending over a given period with money at a given rate. For the present value of an annuity of any sum, multiply the tabular number by the sum. Table 34, Sec. 22, gives the annuity which will amount to one dollar in a given time at a given rate. (Tabular numbers are reciprocals of those in Table 32, Sec. 22.) To find the annual payment which will amount to a given sum in a given time at a given rate (SINKING FUND), multiply the tabular number by the sum.

Example. To provide a sinking fund of $100,000 in 20 years if money accumulates at 4%, the annual sum to be set aside equals 100,000 × 0.033582 (tabular number in Table 34, Sec. 22, opposite 20 years under 4%), that is, $3,358.20.

Cost of an annuity. Annuity which a given sum P will purchase, when the annuity is to extend over a given period and money is worth a given rate, is found as follows: add the given rate in cents to the tabular number in Table 34, Sec. 22, which corresponds to period and rate, and multiply the sum by P.

Example. For 20 years at rate 4% the tabular number in Table 34, Sec. 22, is 0.033582. Adding 0.04 gives 0.073582. Hence \$100,000 will purchase an annuity of \$7,358.20 terminating after 20 years, when money is worth 4%.

Mine valuation (8). The annual profit earned by a mine may be regarded as an annuity which must provide a dividend return on capital plus an annual sum to be set aside for a sinking fund that will amortize the capital. The value of the mine is the present value of the annual profit so regarded. If P = the annual profit considered assured for a period of years, value of mine is found as follows: Find the tabular number for period and rate earned by payments into sinking fund from Table 34, Sec. 22. Add the dividend on one dollar to this number and divide the annual profit by the sum. (Table 9, Sec. 22, is useful to replace division by multiplication.)

Example. Annual profit is estimated at \$200,000 for 10 years. Payments into sinking fund earn 4% and dividend on capital invested is 7%. Tabular number (Table 34) for 10 years and 4% is 0.083291. Adding dividend rate 0.07, gives 0.153291. Reciprocal of 0.1533 (Table 9, Sec. 22) = 6.523. Present value of mine = 6.523 × 200,000 = \$1,304,600.

Amortization. To determine the number of years that a given rate of income on capital must continue in order to amortize capital, pay a given rate of interest on capital, with annual payments into a sinking fund accumulating at a given rate per cent., proceed as follows: In Table 34, Sec. 22, in the column under "Rate of accumulating sinking fund," find the number equal to the difference between the rate of income earned and the dividend rate. Then the time required is the corresponding value of time in the first column (interpolation may be used if justified by the problem).

Example. Rate of income earned is 10%, dividends paid 7%, sinking fund accumulates at 4%. Then from Table 34, under 4%, number 0.03(= 0.10 − 0.07) occurs for a time between 21 and 22 years. (Interpolation gives 21.6 years.)

ELEMENTARY GEOMETRY

13. PLANE FIGURES

Triangles. Sum of angles equals 180°. Exterior angle equals the sum of the opposite interior angles ($\angle XAB = \angle B + \angle C$, Fig. 6, item *a*). MEDIAN is the line joining a vertex to the midpoint of the opposite side; the medians (item *a*) meet in a point G, which is the center of gravity of the triangle; G trisects each median. BISECTORS OF ANGLES meet in a point M (item *b*) equidistant from all sides, and therefore the center of the inscribed circle (INCENTER). The bisector of an angle divides the opposite side into segments proportional to the other two sides, *i.e.*, $AE : EC = AB : BC$ (item *b*). ALTITUDES of a triangle meet in a point (ORTHOCENTER). The perpendicular bisectors of the sides of a triangle meet in a point O (item *c*) equidistant from all vertices, and therefore the center of the circumscribed circle (CIRCUMCENTER). The longest side of a triangle is opposite the largest angle and *vice versa*. The line joining the mid-points of two sides of a triangle is parallel to the third side and half its length.

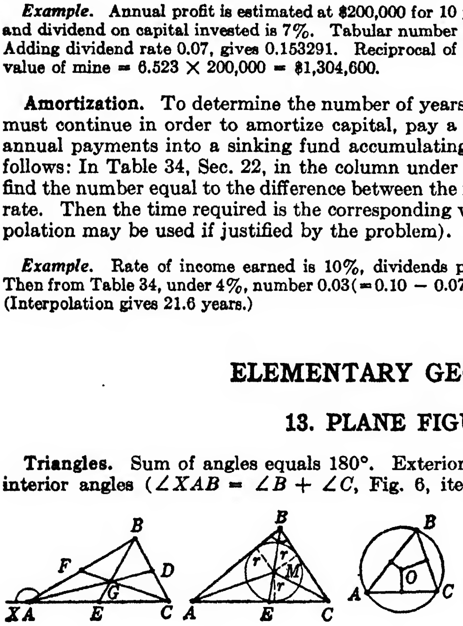

FIG. 6. Triangles; medians, inscribed and circumscribed circles.

Orthogonal projection. In Fig. 7, items *a*, *b*, AE is the ORTHOGONAL PROJECTION of AB on AC, BE being perpendicular to AC. The square of the side opposite an acute angle equals the sum of the squares of the other two sides diminished by twice the product of one of these sides by the orthogonal projection of the other side upon it. In item *a*, $a^2 = b^2 + c^2 - 2b\cdot AE$. The square of the side opposite an obtuse angle equals the sum of the squares of the other two sides increased by twice the product of

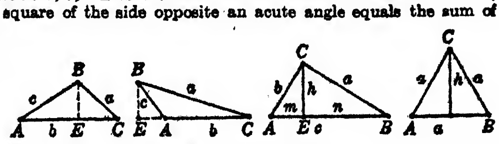

FIG. 7. Triangles.

one of these sides by the orthogonal projection of the other side upon it. In item *b*, $a^2 = b^2 + c^2 + 2b \cdot AE$.

Right triangle (Fig. 7, item *c*). $\angle A + \angle B = 90°$. $c^2 = a^2 + b^2$. The ALTITUDE CE ($= h$) drawn from vertex of right angle C upon HYPOTENUSE (c), divides the hypotenuse into segments AE ($= m$) and BE ($= n$) such that $h^2 = mn$, $b^2 = cm$, $a^2 = cn$. The median drawn from C equals $1/2\ c$.

Equilateral triangle (Fig. 7, item *d*). Side $= a$. Each angle $= 60°$. ALTITUDE, $h = 1/2\, a\sqrt{3}$. RADIUS OF CIRCUMSCRIBED CIRCLE, $R = 1/3\, a\sqrt{3}$. RADIUS OF INSCRIBED CIRCLE, $r = 1/6\, a\sqrt{3}$.

Trapezoid is a figure bounded by four lines, two of which are parallel (Fig. 8). ALTITUDE is the perpendicular distance between the parallel sides. MID-LINE (EF) joins the mid-points of the non-parallel sides and equals half the sum of the parallel sides. ($m = (a + b)/2$).

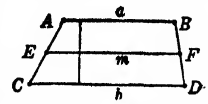

FIG. 8. Trapezoid.

Polygon. Sum of interior angles equals 180° multiplied by the number of sides less two.

Circles. Straight line perpendicular to a radius at its extremity is tangent. Parallel lines intercept equal arcs. When two circles intersect, the LINE OF CENTERS bisects the common chord at right angles. If two circles are tangent to each other, the line of centers passes through the point of contact. AREAS OF TWO CIRCLES have the same ratio as the squares of their diameters or radii.

Angle measurement. The angle inscribed in a semi-circle is a right angle. The angle formed by two chords intersecting on a circle (INSCRIBED ANGLE) is measured by half the arc intercepted between its sides ($\angle BAC$ (Fig. 8A, item *a*) measured by half BC). Angle formed by a tangent and a chord drawn from the point of contact is measured by half the intercepted arc ($\angle BAT$ (item *a*) measured by $1/2\ BCA$). Angle formed by two chords intersecting within a circle is measured by half the sum of the intercepted arcs ($\angle BAC$ (or EAF) (item *b*) measured by $1/2$ (arc BC + arc EF)). Angle formed by two secants, or two tangents, or a tangent and a secant, intersecting without a circle, is measured by half the difference of the intercepted arcs. In item *c*, $\angle BAC$ is measured by $1/2$ (arc BC − arc EF); in item *d*, $\angle BAE$ is measured by $1/2$ (arc BDE − arc BCE), and $\angle BAC$ is measured by $1/2$ (arc BD − arc BC).

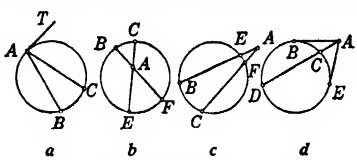

FIG. 8A. Angle measurement.

Chords, secants, and tangents. In Fig 8*A*, item *b*, the product of segments AC and AE equals the product of segments AB and AF. In item *c*, the product of the whole secant AB and the external segment AE equals the product of the whole secant AC and its external segment AF. In item *d*, the product of the whole secant AD and the external segment AC equals the square of tangent AB (or AE).

Similar figures. Similar polygons have their angles respectively equal and the homologous sides proportional. TRIANGLES ARE SIMILAR if their angles are respectively equal, or if their sides are respectively proportional, or if they have an angle of one equal to an angle of the other and the including sides proportional. AREAS of similar polygons are to each other as the squares of homologous sides.

Regular figures. A regular polygon is one with equal sides and equal angles. A circle may be drawn to pass through all vertices of a regular polygon (CIRCUMSCRIBED CIRCLE), or to be tangent to every side (INSCRIBED CIRCLE). Two regular polygons of the same number of sides are similar.

Geometrical Constructions

Lines. To BISECT A STRAIGHT LINE. AB (Fig. 9, item *a*); with A and B as centers and with equal radii sufficiently great, describe arcs intersecting at C and D; draw CD, cutting AB at E, the mid-point of AB.

To ERECT A PERPENDICULAR AT A POINT C, in a line AB (Fig. 9, item *c*). (1) Lay off $CD = CE$, and with D and E as centers and with equal radii sufficiently great, describe arcs intersecting at F; draw FC, the perpendicular required. Or (2), (item *d*), take any convenient point D not on AB and with radius DC describe a circle cutting AB at E. Draw diameter EDF. Then FC is the required perpendicular.

To DROP A PERPENDICULAR FROM A POINT C to a line AB (item *e*). (1) With C as center and a radius sufficiently great, describe an arc cutting AB at D and E; with D and E as centers, describe arcs intersecting at F; draw CF, the required perpendicular. (2) When C is nearly above one end of the line (item *f*), with C as center and radius 5 convenient units describe an arc cutting AB at D. Lay off DF equal to 4 units and draw CF, the required perpendicular.

To DRAW A LINE THROUGH A POINT C PARALLEL to given line AB (item *g*), draw CD perpendicular to AB, and erect a perpendicular CE to CD at C; CE is parallel to AB.

To DRAW A LINE PARALLEL TO A GIVEN LINE AB at a given distance from it (item *h*); with the given distance as radius and with any centers m and n on AB describe arcs xy and zw, respectively; CD, touching these arcs, is the required line.

To DIVIDE A LINE AB into a given number of equal parts (item *i*), draw AD making any angle with AB and draw BC parallel to AD; with dividers lay off equal lengths on AD and BC a number of times one less than the number of equal parts into which AB

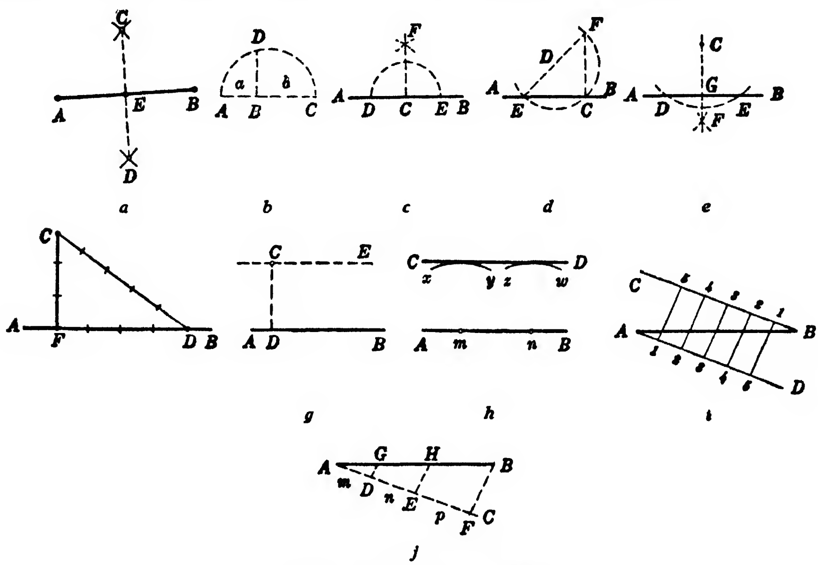

FIG. 9. Construction of lines.

is to be divided; number the points of division consecutively from A and from B and join as in the figure; the connecting lines divide AB as required.

To divide a given line AB into segments proportional to any number of given lines (item *j*), draw AC, making any convenient angle with AB; lay off AD, DE, and EF equal to the given lines m, n, p; draw FB, and construct EH and DG parallel to FB; AG, GH, HB are the required segments.

To CONSTRUCT THE MEAN PROPORTIONAL between two given lines (item *b*), draw a line AC on which AB and BC equal the given lines, a, b; construct semi-circle on AC as diameter; erect a perpendicular to AC at B, intersecting the semi-circle at D; BD is the mean proportional between AB and BC.

Angles. To BISECT a given angle CAB (Fig. 10, item *a*), with A as center, and with any convenient radius AD describe an arc cutting AC in D and AB in E; with D and E as centers and with equal radii sufficiently great, describe arcs intersecting in F; AF bisects $\angle A$.

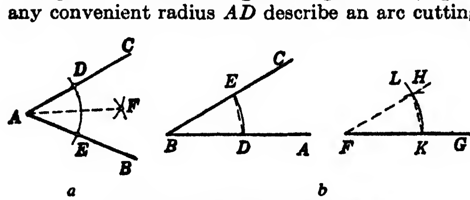

FIG. 10. Construction of angles.

To CONSTRUCT AN ANGLE EQUAL TO A GIVEN ANGLE ABC when one side FG and the vertex F are given (item *b*), with center B and a convenient radius BD describe arc DE; with the same radius and center F, draw arc KL; with radius equal to chord DE and with center K draw an arc cutting the arc KL at H; HFG is the required angle.

Circles. To CIRCUMSCRIBE a circle about a given triangle (Fig. 11, item *a*), construct perpendicular bisectors of two sides; their point of intersection is the required circumcenter.

To INSCRIBE a circle in a given triangle (item *b*), draw bisectors of two angles intersecting in O (incenter); from O, draw OD perpendicular to BC; a circle with center O and radius OD is the required circle.

To DRAW A TANGENT to a given circle through a given point P: (1) *When P is on circle* (item *c*), draw radius OP, and construct AB perpendicular to OP at P; AB is the required

tangent. (2) *When P is without the circle* draw a line joining P and O, the center of circle (item *d*); with OP as diameter describe a circle intersecting the given circle at A and B; draw PA and PB, each of which is tangent to the given circle.

To DRAW A COMMON TANGENT to two given circles, with centers O and O' and unequal radii r and r', $r > r'$. (1) When the given circles do not intersect (item *f*), to draw a

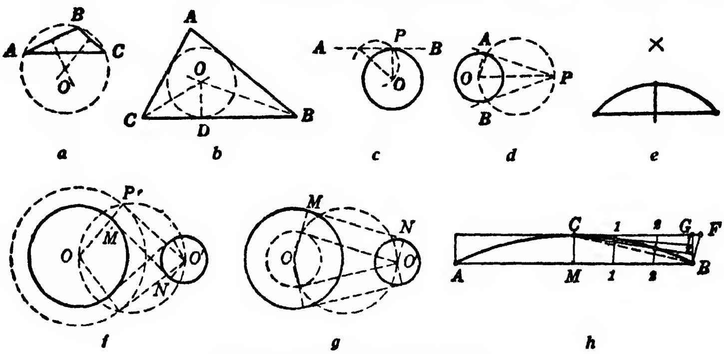

FIG. 11. Construction of circles.

COMMON INTERNAL TANGENT, construct a circle having same center O as larger circle and a radius equal to the sum of the radii of the given circles $(r + r')$; construct a tangent $O'P'$ from center O' of the small circle to this circle; construct $O'N$ perpendicular to this tangent; draw OP'; then line MN, joining the extremities of the radii OM and $O'N$, is a common tangent. Item *f* shows two such common internal tangents. (2) To draw a COMMON EXTERNAL TANGENT (item *g*), construct a circle having a common center with the larger circle and radius equal to the difference of radii $(r - r')$; construct a tangent to this circle from the center of the smaller circle; the line joining the extremities M, N, of the radii of the given circles perpendicular to this tangent is the required common tangent. There are two such tangents.

In item *f*, $MN = \sqrt{c^2 - (r + r')^2}$, when $OO' = c$. In item *g*, $MN = \sqrt{c^2 - (r - r')^2}$.

To BISECT A GIVEN ARC of a circle, draw the perpendicular bisector of the chord of the arc (item *e*); the point in which this bisector meets the arc is the required mid-point.

To LAY OUT A CIRCULAR ARC OF LARGE RADIUS (item *h*). Let AB be the chord of the desired arc and MC the height, MC being the perpendicular bisector of AB; draw CB, and at B erect BF perpendicular to CB and BG perpendicular to AB; divide CF, MB, BG into the same number of equal parts; connect corresponding points of division on CF and MB, and draw lines from C to points of division on BG, as in the figure. In this manner as many points on the required arc can be determined as desired.

Let $CM = h$, $AB = 2b$. Then radius of arc $= (b^2 + h^2)/2h$.

Loci. All points equidistant from a given point lie on a circle whose center is the given point. All points equidistant from two given points lie on perpendicular bisector of the line joining the given points. All points equidistant from the sides of a given angle lie on the bisector of the angle. If a point moves so that the ratio of its distances from two fixed points remains constant, it will lie upon a circle. In Fig. 12, item *a*, PA/PB remains constant while P describes the circle. Diameter DE is determined by drawing bisectors of angles APB and BPE. If a side AB and the opposite angle of a triangle (Fig. 12, item *b*) are given, vertex E of angle will lie on a circle of which the given side is a chord. This circle is constructed as follows: construct $\angle ABC$ equal to the given angle; erect BM perpendicular to CB and draw the perpendicular bisector DP of AB; the point of intersection of BM and DP is the center of the required circle.

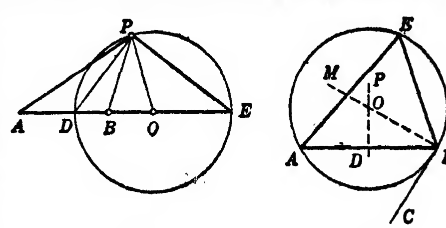

FIG. 12. Circular loci.

Polygons. To construct a SQUARE WITH A GIVEN SIDE AB (Fig. 13, item *a*), erect a perpendicular at A, lay off $AC = AB$, and from C and B as centers, with radius equal to AB, describe arcs intersecting at the fourth vertex D.

To construct a SQUARE WITH A GIVEN DIAGONAL AC (item b), draw a circle on AC as diameter, and erect the diameter BD perpendicular to AC; $ABCD$ is the required square.

To inscribe a SQUARE IN A GIVEN CIRCLE, draw perpendicular diameters AC and BD (item b); their extremities are the vertices of the inscribed square.

To inscribe a HEXAGON IN A CIRCLE, step around the circle with dividers set to the radius (item c).

To construct a HEXAGON WITH A SIDE OF GIVEN LENGTH, draw a circle with radius equal to given side, and inscribe a regular hexagon in this circle. If the side of a regular hexagon $= a$, and the distance between parallel sides $= d$, then $d = a\sqrt{3} = 1.732a$.

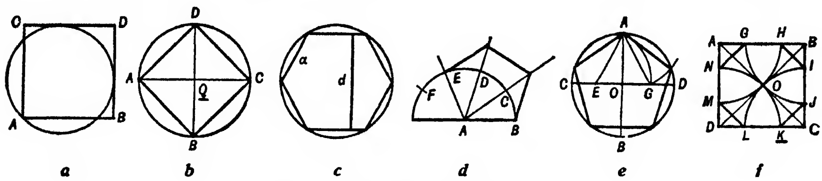

FIG. 13. Construction of polygons.

To draw a REGULAR POLYGON of any desired number of sides, when one side AB is given, draw a semi-circle with radius AB (item d), and divide this semi-circle into as many equal parts BC, CD, DE, etc., as the required polygon has sides; draw a line from A through each point of division except the last, and complete the construction as indicated.

To inscribe a REGULAR PENTAGON in a given circle, draw perpendicular diameters AB and CD (item e); bisect radius OC at E; with E as center, strike an arc through A cutting OD at G; AG equals a side of the pentagon required.

To inscribe a REGULAR OCTAGON in a circle, draw perpendicular diameters, and bisect each of the four equal arcs determined by the extremities of these diameters.

To convert a SQUARE INTO AN OCTAGON, draw diagonals AC and BD, intersecting at O (item f); with vertices A, B, C, D as centers and radius AO draw arcs cutting the sides of the square in eight points; these intersections are the required vertices.

Mensuration of Plane Figures

Square. Side $= a$, diagonal $= d$.

$d = a\sqrt{2} = 1.414a.$ $\quad a = \frac{1}{2}d\sqrt{2} = 0.707d.$ $\quad$ *Area* $= a^2 = \frac{1}{2}d^2.$

Rectangle. Sides $= a, b$; diagonal $= d$.

$d^2 = a^2 + b^2.$ $\quad$ *Area* $= ab.$

Parallelogram. Sides $= a, b$; altitude on side $a = h$; diagonals $= d_1, d_2$; acute angle at vertex $= C$.

$d_2^2 = a^2 + b^2 - 2ab\cos C.$ $\quad d_1^2 = a^2 + b^2 + 2ab\cos C.$

$d_1^2 + d_2^2 = 2(a^2 + b^2).$ $\quad$ *Area* $= ah.$

Rhombus. Each side $= a$; diagonals $= d_1, d_2$.

$d_1^2 + d_2^2 = 4a^2.$ $\quad$ *Area* $= \frac{1}{2}d_1d_2.$

Trapezoid. Parallel sides $= a, b$; altitude $= h$; mid-line (EF, Fig. 8) $= m$.

Area $= \frac{1}{2}h(a + b) = hm.$

Triangle. Sides $= a, b, c$; angles $= A, B, C$ (see Fig. 7 for correspondence between lettering of sides and angles); altitude on side $a = h$; radius of inscribed circle $= r$, radius of circumscribed circle $= R$. Let $s = \frac{1}{2}(a + b + c)$.

$r = \sqrt{(s-a)(s-b)(s-c)/s};$ $\quad R = \frac{1}{2}a/\sin A = \frac{1}{2}b/\sin B = \frac{1}{2}c/\sin C.$

Area $= \frac{1}{2}$ *base* $\times$ *altitude* $= \frac{1}{2}ah = \frac{1}{2}ab\sin C = \frac{1}{2}bc\sin A = \frac{1}{2}ca\sin B = rs = \frac{1}{4}abc/R = \sqrt{s(s-a)(s-b)(s-c)} = 2R^2\sin A\sin B\sin C = r^2\cot\frac{1}{2}A\cot\frac{1}{2}B\cot\frac{1}{2}C = \frac{1}{2}a^2\sin B\sin C/\sin A.$

Length of median from vertex A $= \frac{1}{2}\sqrt{2(a^2 + b^2) - c^2}.$

Length of bisector of angle A $= \sqrt{ab[(a + b)^2 - c^2]/(a + b)}.$

Equilateral triangle. Side $= a$; altitude $= h$.

$h = {}^1/_2 a\sqrt{3} = 0.86603a$. $\qquad$ *Area* $= {}^1/_4 a^2\sqrt{3} = 0.43301a^2$.

Right triangle. Sides $= a, b$; hypotenuse $= c$.

$c^2 = a^2 + b^2$. $\qquad$ *Area* $= {}^1/_2 ab = {}^1/_2 a^2 \tan B = {}^1/_2 a^2 \cot A = {}^1/_4 c^2 \sin 2A$.

Any quadrilateral. Sides $= a, b, c, d$; diagonals $= d_1, d_2$ forming acute angle D; line joining mid-points of diagonals $= m$.

$a^2 + b^2 + c^2 + d^2 = d_1^2 + d_2^2 + 4m^2$. $\qquad$ *Area* $= {}^1/_2 d_1 d_2 \sin D$.

Quadrilateral inscribed in a circle (Fig. 14). Sum of opposite angles $= 180°$. Sides $= a, b, c, d$; angle formed by sides a and $b = X$; diagonals $= e, f$. Let $s = {}^1/_2(a + b + c + d)$.

$ac + bd = ef$. $\qquad$ *Area* $= \sqrt{(s - a)(s - b)(s - c)(s - d)} = (ab + cd) \sin X$.

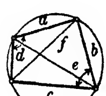

Fig. 14. Inscribed quadrilateral.

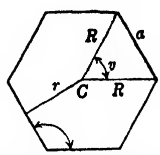

Fig. 15. Regular polygon.

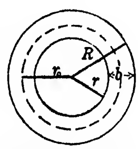

Fig. 16. Annulus.

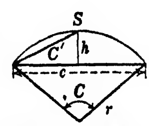

Fig. 17. Sector and segment.

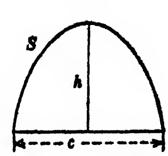

Fig. 18. Parabolic segment.

Regular polygons (Fig. 15). Side $= a$, number of sides $= n$.

Vertex angle $= 360°(n - 2)/n$. $\qquad$ *Central angle* (as v) $= 360°/n$.

$r = {}^1/_2 a \cot {}^1/_2 v = {}^1/_2 a \tan {}^1/_2 A$. $\qquad$ $R = {}^1/_2 a/\sin {}^1/_2 v = {}^1/_2 a/\cos {}^1/_2 A$.

Area $= {}^1/_2 nar = a^2({}^1/_4 n \cot {}^1/_2 v) = a^2 k$. $\quad k$, see Table 4.

Table 4. Values of k for area of regular polygon

n	3	4	5	6	7	8	9	10	11	12
k	0.433	1.000	1.720	2.598	3.634	4.828	6.182	7.694	9.366	11.196

Circle. Radius $= r$, diameter $= d$. See Tables 10, 11, Sec. 22.

Ratio of circumference to diameter $= \pi = 3.1415927$.

Circumference $= 2\pi r = \pi d$. $\qquad$ *Area* $= \pi r^2 = {}^1/_4 \pi d^2 = 0.7854d^2$.

Circular ring (ANNULUS). (Fig. 16.) Outer radius $= R$, inner radius $= r$, mean radius $= r_0$, width $= b$.

$r_0 = {}^1/_2(R + r)$. $\qquad$ $b = R - r$.

Area $= \pi(R^2 - r^2) = \pi(R + r)(R - r) = 2\pi r_0 b$.

Circular arc. Radius $= r$, length of arc $= S$, central angle $= C$.

$S = rC$ (C in radians) $= \pi rC/180 = 0.01745rC$ (C in degrees). See Tables 14 to 17, Sec. 22. If chord of arc (Fig. 17) $= c$, and chord of half the arc $= C'$, then $S = 2C' + {}^1/_3(2C' - c)$ approximately (HUYGHEN'S FORMULA).

Circular sector (Fig. 17). *Area* $= {}^1/_2 Sr = {}^1/_2 r^2 C$ (C in radians) $= \pi r^2 C/360 = 0.008727r^2 C$ (C in degrees).

Circular segment (Fig. 17). Height of segment $= h$, chord $= c$, chord of half arc $= C'$.

$C'^2 = 2hr \qquad c = 2r \sin {}^1/_2 C \qquad h = r(1 - \cos {}^1/_2 C) \qquad r = ({}^1/_4 c^2 + h^2)/2h$

Area $= {}^1/_2 r^2(C - \sin C)$, where angle C is in radians, $= {}^1/_2(rS + ch - cr)$.

Approximate formula: *Area* $= {}^4/_3 h^2\sqrt{2r/h - 0.608}$. See also Table 12, Sec. 22.

Parabolic segment (Fig. 18). Chord $= c$, height $= h$, arc $= S$.

Area $= {}^2/_3 ch$. $\qquad$ $S = {}^1/_2\sqrt{c^2 + 16h^2} + \dfrac{c^2}{8h}$ Nap log $(4h + \sqrt{c^2 + 16h^2})/c$.

Area between two chords c and C (parallel and at a distance d apart) $= {}^2/_3 d \dfrac{C^3 - c^3}{C^2 - c^2}$.

Ellipse (Fig. 19). Semi-axes: major = a, minor = b.

Area between BB′ and PP′ = $xy + ab\sin^{-1}x/a$. *Area of ellipse* = πab.
Area of sector AOP = $^1/_2 ab\cos^{-1}x/a$. *Perimeter of ellipse* = $4aE$.

Values of E for $t = b/a$ are in Table 5.

Table 5. Values of E for perimeter of ellipse

t	0	0.1	0.2	0.3	0.4	0.5	0.6	0.7	0.8	0.9	1.0
E	1.000	1.016	1.051	1.097	1.151	1.211	1.276	1.346	1.418	1.493	1.571

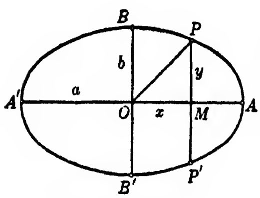

Fig. 19. Ellipse.

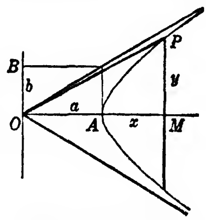

Fig. 20. Hyperbola.

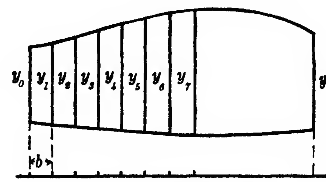

Fig. 21. Irregular area.

Hyperbola (Fig. 20). Semi-axes, transverse = a, conjugate = b.

Area AMP = $^1/_2 xy - {}^1/_2 ab\ln(x/a + y/b)$.
Area OAP = $^1/_2 ab\ln(x/a + y/b) = {}^1/_2 abu$, where $x = a\cosh u$.

Cycloid. (See Fig. 57.) Radius of rolling circle = a.

Length of arc OP = $4a(1 - \cos{}^1/_2\theta)$. *Length of entire arc OMN* = $8a$.
Area between arc OMN and base OX = $3\pi a^2$ = *three times area of rolling circle.*

Epicycloid (Fig. 59).

Arc AP = $4r(R + r)(1 - \cos(R\theta/2r))/R$.
Area AOP = $[r(R + r)(R + 2r)](R\theta/r - \sin R\theta/r)/2R$.

Hypocycloid (Fig. 60). Formulas for arc and area are the same as for epicycloid with sign of r changed.

Catenary (Fig. 64).

Arc BP = $a\sinh x/a = \sqrt{y^2 - a^2}$ where x, y, are co-ordinates of P.
Area OMPB = $a^2\sinh x/a = a\sqrt{y^2 - a^2}$.

Spiral of Archimedes (Fig. 65).

Arc OP = $^1/_2 a[\theta\sqrt{1 + \theta^2} + \ln(\theta + \sqrt{1 + \theta^2})]$ (θ in radians).

Simpson's rule for approximate measure of an area (Fig. 21). Divide the area by equidistant parallel lines into an even number n of strips each of width b, and denote the lengths of the parallel sides of these strips successively by $y_0, y_1, y_2, y_3, \ldots, y_n$. Then an approximate value for the area is

$$Area = {}^1/_3 b(y_0 + 4y_1 + 2y_2 + 4y_3 + 2y_4 + \ldots + 4y_{n-1} + y_n), \text{ or}$$
$$= {}^1/_3 b[(y_0 + y_n) + 4(y_1 + y_3 + y_5 + \ldots y_{n-1}) + 2(y_2 + y_4 + y_6 + \ldots y_{n-2})].$$

The larger the number of strips the closer the approximation.

14. MENSURATION OF SOLIDS

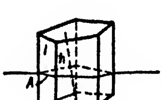

Fig. 22. Prism.

Prism (Fig. 22) is a solid, any transverse section of which is a polygon, and the bases of which are parallel, similar, and equal in area. Perimeter of a plane section A cutting all edges at right angles (RIGHT SECTION) = c; length of lateral edge = l; altitude (perpendicular distance between upper and lower bases) = h, area of base = B.

Lateral surface = cl. *Volume* = Bh.

Right-circular cylinder. Diameter of base = d, altitude = h.

Lateral surface = πdh. *Total surface* = $\pi d(h + {}^1/_2 d)$. *Volume* = $\pi d^2h/4$.

Truncated right-circular cylinder. Diameter of circular base = d, arithmetic mean of longest and shortest elements = h.

Lateral surface = πdh. *Volume* = $\pi d^2h/4$.

Truncated triangular prism. Area of base = B, lengths of edges = a, b, c.

Volume = $^1/_3B(a + b + c)$.

Ungula of right-circular cylinder (Fig. 23). Base is a circular segment with central angle $2a$ (radians) and area B.

Lateral area = $hr(2 \sin a - a \cos a)/(1 - \cos a)$.
Volume = $h(^2/_3r^2 \sin^3 a - B \cos a)/(1 - \cos a)$.

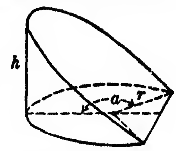

Fig. 23. Ungula.

Hollow right-circular cylinder. Outer and inner diameters = D, d, altitude = h, thickness = t.

Volume = $\pi ht(D + d)/2$.

Regular pyramid. Base is a regular polygon; lateral faces are equal isosceles triangles. Side of base = a, area of base = B, altitude of a lateral face (slant height of pyramid) = s, altitude of pyramid = h.

Lateral area = $^1/_2nas$. *Volume* = $^1/_3Bh$.

Right-circular cone. Radius of base = r, slant height = s, altitude = h.

$s = \sqrt{h^2 + r^2}$. *Lateral area* = πrs. *Total area* = $\pi r(s + r)$.
Volume = $^1/_3\pi hr^2$.

Frustum of a regular pyramid (bases parallel). Altitude of a lateral face (slant height of frustum) = s, perimeters of bases = p, P; areas of bases = b, B; altitude of frustum = h.

Lateral area = $^1/_2s(p + P)$. *Volume* = $^1/_3h(B + b + \sqrt{Bb})$.

Frustum of right-circular cone (bases parallel). Slant height = s, radii of bases = r_1, r_2, altitude = h.

$s = \sqrt{h^2 + (r_2 - r_1)^2}$. *Lateral area* = $\pi s(r_1 + r_2)$.
Total area = $\pi(r_1^2 + r_2^2 + s(r_1 + r_2))$. *Volume* = $^1/_3\pi h(r_1^2 + r_2^2 + r_1r_2)$.

Any pyramid or cone. Altitude = h, area of base = B.

Volume = $^1/_3Bh$.

Frustum of any pyramid or cone. Altitude = h, areas of bases = b, B.

Volume = $^1/_3h(B + b + \sqrt{Bb})$.

Regular polyhedra. Edge = a.

	Tetrahedron	Cube	Octahedron	Dodecahedron	Icosahedron
Area......	$1.7321a^2$	$6a^2$	$3.4641a^2$	$20.646a^2$	$8.6603a^2$
Volume...	$0.1179a^3$	a^3	$0.4714a^3$	$7.6631a^3$	$2.1817a^3$

Sphere. Radius = r, diameter = d.

Area = $4\pi r^2 = \pi d^2$ = *area of four great circles.*
Volume = $^4/_3\pi r^3 = {}^1/_6\pi d^3$. See also Table 13, Sec. 22.

Spherical polygon is a figure on a spherical surface bounded by three or more arcs of great circles. The sum of the angles of a spherical triangle is greater than two right angles and less than six right angles. Two spherical polygons on the same sphere or on equal spheres are SYMMETRIC if the sides and angles of one are respectively equal to those of the other, but arranged in reverse order. Symmetric spherical polygons have equal areas. Sum of angles in degrees = S, number of sides = n. Spherical excess = E = $S - (n - 2)180$ (in degrees).

Area = $\pi r^2E/180$.

Zone is a portion of a spherical surface included between two parallel plane sections. Altitude = h (perpendicular distance between parallel planes), radius of sphere = r.

Area of zone = $2\pi rh$ (product of circumference of a great circle and altitude of zone).

Spherical segment is the portion of sphere included between two parallel plane sections, called bases. Radii of bases = b, B; altitude of segment = h (perpendicular distance between bases).

Volume = $^1/_2\pi h(B^2 + b^2 + {}^1/_3h^2)$.

Wedge (Fig. 24). Base $DEFC$ is a rectangle, $CF = b$, $EF = L$, edge $AB = l$, at perpendicular distance $RS = h$ from base.

Volume $= {}^1/_6 bh(2L + l)$.

Prismatoid. Bases are polygons in parallel planes, areas $= b$, B. Lateral faces are trapezoids or triangles whose vertices coincide with certain vertices of the bases. Altitude $= h$ (perpendicular distance between bases), area of plane section midway between bases $= m$.

Volume $= {}^1/_6 h(b + B + 4m)$.

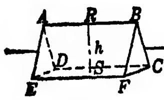

FIG. 24. Wedge.

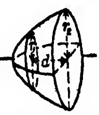

FIG. 25. Segment of paraboloid.

FIG. 26. Ellipsoid.

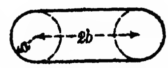

FIG. 27. Torus.

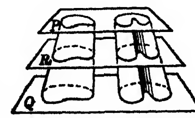

FIG. 28. Cavalieri's theorem.

Segment of paraboloid (Fig. 25). Radii of bases $= r_1, r_2$; altitude $= d$.

Volume $= {}^1/_2 \pi d(r_1^2 + r_2^2)$.

Ellipsoid (Fig. 26). Semi-axes $= a, b, c$ *Volume* $= {}^4/_3 \pi abc$.

Torus (ANCHOR RING). (Fig. 27).

Area $= 2\pi a \times 2\pi b = 4\pi^2 ab$. *Volume* $= \pi a^2 \times 2\pi b = 2\pi^2 a^2 b$.

Theorems of Pappus. (1) If any closed plane figure is revolved about an exterior axis in its own plane, the volume of the solid generated equals the product of the area of the plane figure by the length of the circular path described by its center of gravity. (2) If a plane curve is revolved about an exterior axis in its plane, the area of the surface generated equals the product of the arc of the curve by the length of the circular path described by its center of gravity. These theorems are useful in determining centers of gravity when other quantities involved are known, and also in calculating areas and volumes when centers of gravity are given.

Cavalieri's theorem (Fig. 28). If two solids are included between a pair of parallel planes, and if the two sections cut from them by any plane parallel to the including planes are equal in area, then the volumes of the solids are equal.

TRIGONOMETRY

15. FUNCTIONS OF AN ACUTE ANGLE

Definitions. In Fig. 29 take any point B on either side AD of angle A, and draw BC perpendicular to the other side AE, forming the right triangle BAC. In this triangle, for angle A, $BC (= a)$ is called OPPOSITE SIDE, and AC $(= b)$ ADJACENT SIDE. The trigonometric functions of A are sine, cosine, tangent, cotangent, secant, and cosecant, defined respectively as follows:

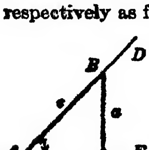

FIG. 29. Angle A.

$$\sin A = \frac{\text{opposite side}}{\text{hypotenuse}} = \frac{a}{c}, \qquad \csc A = \frac{\text{hypotenuse}}{\text{opposite side}} = \frac{c}{a},$$

$$\tan A = \frac{\text{opposite side}}{\text{adjacent side}} = \frac{a}{b}, \qquad \cot A = \frac{\text{adjacent side}}{\text{opposite side}} = \frac{b}{a},$$

$$\cos A = \frac{\text{adjacent side}}{\text{hypotenuse}} = \frac{b}{c}, \qquad \sec A = \frac{\text{hypotenuse}}{\text{adjacent side}} = \frac{c}{b}.$$

Sine and cosine are called CO-FUNCTIONS of each other, as also are tangent, and cotangent, secant and cosecant.

Versine of A = **vers** $A = 1 - \cos A$. Coversine of A = **covers** $A = 1 - \sin A$. **Haversine** of A = **havers** $A = {}^1/_2 (1 - \cos A)$.

Functions of complementary angles. In the right triangle ABC (Fig. 29), angles A and B are COMPLEMENTARY ANGLES (sum $= 90°$). Any function of an angle equals the corresponding co-function of the complementary angle. Hence

$\sin A = \cos B$	$\tan A = \cot B$	$\sec A = \csc B$
$\cos A = \sin B$	$\cot A = \tan B$	$\csc A = \sec B$

Functions of special angles. In Fig. 30, triangle ABC is an ISOSCELES RIGHT TRIANGLE, $AC = BC$, angle A = angle $B = 45°$, sides AC and BC are of unit length and $AB = \sqrt{2}$. Triangle ABD is equilateral with sides 2 units in length, each angle is 60°; in right triangle ABC therein, $A = 60°$, $B = 30°$, $BC = \sqrt{3}$. Functions are given in Table 6.

Tables for trigonometric functions and for their logarithms are given in Sec. 22. The values are obtainable, with less precision, by slide rule (Art. 1).

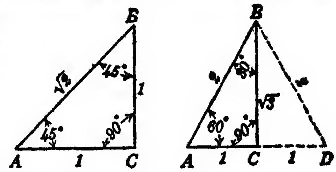

FIG. 30. Angles of 30, 45, and 60 degrees.

Table 6. Functions of special angles

Angle	Sin	Cos	Tan	Cot	Sec	Csc
0° and 360°	0	1	0	∞	1	∞
30°	1/2	$\sqrt{3}/2$	$\sqrt{3}/3$	$\sqrt{3}$	$2\sqrt{3}/3$	2
45°	$\sqrt{2}/2$	$\sqrt{2}/2$	1	1	$\sqrt{2}$	$\sqrt{2}$
60°	$\sqrt{3}/2$	1/2	$\sqrt{3}$	$\sqrt{3}/3$	2	$2\sqrt{3}/3$
90°	1	0	∞	0	∞	1
180°	0	−1	0	∞	−1	∞
270°	−1	0	∞	0	∞	−1

Relations Between Functions

$\sin^2 A + \cos^2 A = 1$ $\qquad \sec^2 A = 1 + \tan^2 A$ $\qquad \csc^2 A = 1 + \cot^2 A$

$\sin A = 1/\csc A$ $\qquad \tan A = 1/\cot A$ $\qquad \sec A = 1/\cos A$

$$\sin A = \sqrt{1 - \cos^2 A} = \tan A/\sqrt{1 + \tan^2 A} = 1/\sqrt{1 + \cot^2 A}$$
$$= \sqrt{\sec^2 A - 1}/\sec A = 1/\csc A.$$
$$\tan A = \sin A/\sqrt{1 - \sin^2 A} = \sqrt{1 - \cos^2 A}/\cos A = 1/\cot A$$
$$= \sqrt{\sec^2 A - 1} = 1/\sqrt{\csc^2 A - 1}.$$
$$\cos A = \sqrt{1 - \sin^2 A} = 1/\sqrt{\tan^2 A + 1} = \cot A/\sqrt{\cot^2 A + 1}$$
$$= 1/\sec A = \sqrt{\csc^2 A - 1}/\csc A.$$

Angles of Any Magnitude

An angle is considered as generated by a GENERATING LINE which first coincides with the INITIAL SIDE of the angle, then revolves about the vertex and finally coincides with the TERMINAL SIDE. An angle generated counterclockwise is POSITIVE; clockwise, NEGATIVE. The generating line may make any number of complete revolutions before coinciding finally with the terminal side.

Quadrants (Fig. 31). Angles between 0° and 90° lie in the first quadrant, between 90° and 180° in second, etc. For *negative* angles, those between 0° and −90° lie in the fourth quadrant, between −90° and −180° in third, etc. Addition to or subtraction from an angle of multiples of 360° gives an angle of different magnitude but the same terminal side, hence in the same quadrant.

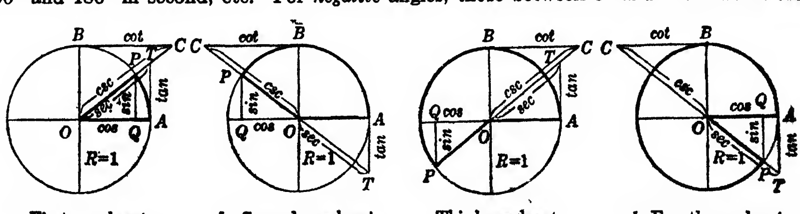

FIG. 31. Line definitions of angle functions.

Line definitions. In Fig. 31, the ratio definitions of the functions of angle AOP are replaced by line definitions as marked, the unit of length being the radius of the circle (UNIT CIRCLE). For an OBTUSE ANGLE (angle between 90° and 180°), the functions are defined for angle AOP as in item *b*. Conventions (in all items) as to positive and negative are: horizontal lines OQ (= cosine) and BC (= cotangent)

to the right of the vertical diameter are positive, to left are negative. Vertical line as PQ (= sine) above horizontal diameter is positive (items a, b); below (items c, d) is negative. Diagonals, *e.g.*, OC (= cosecant) if extending *along* terminal side OP, are positive; whereas if measured along OP *produced* (*e.g.*, OT, item b) they are negative.

Functions of an angle in any quadrant. To write down the numerical values of functions of an angle of any magnitude, express the angle in degrees, and, if necessary, add or subtract multiples of 360° until the magnitude lies between 0° and 360°. Observe in what quadrant the angle lies. If in the first quadrant, the functions are given by Tables 18 and 19, Sec. 22. If in other quadrants, express in one of the forms in column A, Table 7, and read under the desired function the corresponding function of the angle less than 90°, which may then be found from Table 18 or 19, Sec. 22.

Table 7. Functions of an angle from 90° to 360°

A	Sin A	Cos A	Tan A	Cot A	Sec A	Csc A
$90° + x$	$\cos x$	$-\sin x$	$-\cot x$	$-\tan x$	$-\csc x$	$\sec x$
$180° - x$	$\sin x$	$-\cos x$	$-\tan x$	$-\cot x$	$-\sec x$	$\csc x$
$180° + x$	$-\sin x$	$-\cos x$	$\tan x$	$\cot x$	$-\sec x$	$-\csc x$
$270° - y$	$-\cos y$	$-\sin y$	$\cot y$	$\tan y$	$-\csc y$	$-\sec y$
$360° - x$	$-\sin x$	$\cos x$	$-\tan x$	$-\cot x$	$\sec x$	$-\csc x$
$270° + y$	$-\cos y$	$\sin y$	$-\cot y$	$-\tan y$	$\csc y$	$-\sec y$

Examples. Find sin 108°. Write 108° = 90° + 18°, or 180° − 72°. Hence sin 108° = cos 18° = sin 72° = 0.9511.

To find tan 985° 15′. Reduce to an angle between 0° and 360° by subtracting 2 × 360°. 985° 15′ − 720° = 265° 15′, which is an angle in the third quadrant. 265° 15′ = 180° + 85° 15′ = 270° − (4° 45′). Tan 265° 15′ = tan 85° 15′ = cot 4° 15′ = 13.46. Hence tan 985° 15′ = 13.46.

To find csc (− 385° 20′). Adding 720°, 720° − 385° 20′ = 334° 40′, which is an angle in the fourth quadrant. 334° 40′ = 360° − 25° 20′ = 270° + 64° 40′. Csc 334° 40′ = −csc 25° 20′ = −sec 64° 40′ = −2.337. Hence csc (−385° 20′) = −2.337.

Relations between functions of positive and negative angles which are numerically equal are:

$\sin(-A) = -\sin A$ $\quad$ $\cos(-A) = \cos A$ $\quad$ $\tan(-A) = -\tan A$

$\cot(-A) = -\cot A$ $\quad$ $\sec(-A) = \sec A$ $\quad$ $\csc(-A) = -\csc A$

Angle measurement.

DEGREE MEASURE: The unit, one DEGREE, is the angle at the center of a circle whose intercepted arc equals 1/360th of the circumference.

CIRCULAR MEASURE: The unit is one RADIAN, *i.e.*, the angle at the center of a circle intercepting an arc equal in length to the radius of the circle. For any central angle in a circle, the number of radians in the angle = *length of intercepted arc/length of radius.*

Relation between unit angles. 1 degree = 0.01745 radian = $\pi/180$ radian. 1 radian = 57.2957 degrees = $180/\pi$ degrees. 90° = $\pi/2$ radians. 180° = π radians. 270° = $3\pi/2$ radians. 360° = 2π radians (π = 3.14159265). See also Tables 14, 15, 17, Sec. 22.

Angles for which one function has a given value. All angles whose magnitude is expressible as $n \times 180° + (-1)^n \times A$ where n is any integer, positive or negative, and A is expressed in degrees, have the same sine and cosecant as A. (In radians, $\pi n + (-1)^n A$.) If expressible as $n \times 180° + A$, they have the same tangent and cotangent as A. (In radians, $\pi n + A$.) All angles expressible as $n \times 360° \pm A$ have the same secant and cosine as A. (In radians, $\pi n + A$.)

Example. Solve $2 \sin A - \cos A = 0$ for A. Transposing $\cos A$ to the right-hand member and dividing both members by $\cos A$ gives $2 \sin A/\cos A = 1$, or $\tan A = 1/2$. The value of A between 0° and 90° satisfying this equation is A = 26° 34′. (Table 19, Sec. 22.) Hence the solution is: $n \times 180°$ + 26° 34′, where n is any integer, positive or negative. Angles between 0° and 360° satisfying the equation are 26° 34′, and 206° 34′ ($n = 1$).

Functions of Multiple Angles

Sin 2A $= 2 \sin A \cos A$.
Cos 2A $= \cos^2 A - \sin^2 A = 1 - 2\sin^2 A = 2\cos^2 A - 1$.
Tan 2A $= 2 \tan A/(1 - \tan^2 A)$.
Cot 2A $= (\cot^2 A - 1)/2 \cot A$.
Sin 3A $= 3 \sin A - 4 \sin^3 A$.
Cos 3A $= 4 \cos^3 A - 3 \cos A$.
Tan 3A $= (3 \tan A - \tan^3 A)/(1 - 3 \tan^2 A)$.
Sin 4A $= 4 \sin A \cos A - 8 \sin^3 A \cos A$.
Cos 4A $= 8 \cos^4 A - 8 \cos^2 A + 1$.

Sin $nA = \sin (n-1) A \cos A + \cos (n-1) A \sin A.$

Sin $nA = n \cos^{n-1} A \sin A - \binom{n}{3} \cos^{n-3} A \sin^3 A + \binom{n}{5} \cos^{n-5} A \sin^5 A -$, etc.

Cos $nA = \cos (n-1) A \cos A - \sin (n-1) A \sin A.$

Cos $nA = \cos^n A - \binom{n}{2} \cos^{n-2} A \sin^2 A + \binom{n}{4} \cos^{n-4} A \sin^4 A -$, etc.

Functions of Half Angles

Sin $\frac{1}{2}A = \sqrt{\frac{1}{2}(1 - \cos A)}.$

Cos $\frac{1}{2}A = \sqrt{\frac{1}{2}(1 + \cos A)}.$

Tan $\frac{1}{2}A = \sqrt{1 - \cos A}/\sqrt{1 + \cos A} = \sin A/(1 + \cos A) = (1 - \cos A)/\sin A.$

Powers in Terms of Multiple Angles

Sin² $A = \frac{1}{2}(1 - \cos 2A).$
Cos² $A = \frac{1}{2}(1 + \cos 2A).$
Sin³ $A = \frac{1}{4}(3 \sin A - \sin 3A).$
Cos³ $A = \frac{1}{4}(\cos 3A + 3 \cos A).$

Functions of Sum or Difference of Two Angles

Sin $(A + B) = \sin A \cos B + \cos A \sin B.$
Sin $(A - B) = \sin A \cos B - \cos A \sin B.$
Cos $(A + B) = \cos A \cos B - \sin A \sin B.$
Cos $(A - B) = \cos A \cos B + \sin A \sin B.$
Tan $(A + B) = (\tan A + \tan B)/(1 - \tan A \tan B).$
Tan $(A - B) = (\tan A - \tan B)/(1 + \tan A \tan B).$
Cot $(A + B) = (\cot A \cot B - 1)/(\cot A + \cot B).$
Cot $(A - B) = (\cot A \cot B + 1)/(\cot B - \cot A).$

Sums, Differences, and Products of Functions

Sin A **+ sin** $B = 2 \sin \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B).$
Sin A **− sin** $B = 2 \cos \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B).$
Cos A **+ cos** $B = 2 \cos \frac{1}{2}(A + B) \cos \frac{1}{2}(A - B).$
Cos A **− cos** $B = -2 \sin \frac{1}{2}(A + B) \sin \frac{1}{2}(A - B).$
Tan A **+ tan** $B = \sin (A + B)/\cos A \cos B.$
Tan A **− tan** $B = \sin (A - B)/\cos A \cos B.$
Sin² A **− sin²** $B = \sin (A + B) \sin (A - B).$
Cos² A **− cos²** $B = \cos (A + B) \sin (A - B).$
Cos² A **− sin²** $B = \cos (A + B) \cos (A - B).$
Sin A **sin** $B = \frac{1}{2} \cos (A - B) - \frac{1}{2} \cos (A + B).$
Sin A **cos** $B = \frac{1}{2} \sin (A + B) + \frac{1}{2} \sin (A - B).$
Cos A **cos** $B = \frac{1}{2} \cos (A + B) + \frac{1}{2} \cos (A - B).$

Series

Sin $x = x - \frac{1}{3!} x^3 + \frac{1}{5!} x^5 - \ldots$ for all values of x in radians.

Cos $x = 1 - \frac{1}{2!} x^2 + \frac{1}{4!} x^4 - \ldots$ for all values of x in radians.

Tan $x = x + \frac{1}{3} x^3 + \frac{2}{15} x^5 + \frac{17}{315} x^7 + \cdots - \ldots$ for values of x in radians numerically less than $\frac{1}{2}\pi$.

See also Art. 22.

Trigonometric Functions and Exponentials

Sin $x = \dfrac{e^{ix} - e^{-ix}}{2i}.$ **Cos** $x = \dfrac{e^{ix} + e^{-ix}}{2}.$ **Tan** $x = \dfrac{e^{ix} - e^{-ix}}{e^{ix} + e^{-ix}}.$

$(\mathbf{Cos}\ x + i \sin x)^n = \cos nx + i \sin nx.$

See also Art. 10.

Inverse Functions

The equation $\sin 30° = {}^1/_2$ is also written $30° = \sin^{-1} {}^1/_2$. The expression $\sin^{-1} {}^1/_2$ is called INVERSE SINE of $^1/_2$, or "angle whose sine is $^1/_2$." Similarly $\cos^{-1} a$, $\tan^{-1} a$, $\sec^{-1} a$, $\csc^{-1} a$, $\cot^{-1} a$ are inverse functions.

$\mathrm{Sin}^{-1} a = \cos^{-1}\sqrt{1-a^2} = \tan^{-1} a/\sqrt{1-a^2} = \cot^{-1}\sqrt{1-a^2}/a = \sec^{-1} 1/\sqrt{1-a^2} = \csc^{-1} 1/a$.

$\mathrm{Tan}^{-1} a = \sin^{-1} a/\sqrt{1+a^2} = \cot^{-1} 1/a = \cos^{-1} 1/\sqrt{1+a^2} = \sec^{-1}\sqrt{1+a^2} = \csc^{-1}\sqrt{1+a^2}/a$.

$\mathrm{Cos}^{-1} a = \sin^{-1}\sqrt{1-a^2} = \tan^{-1}\sqrt{1-a^2}/a = \cot^{-1} a/\sqrt{1-a^2} = \sec^{-1} 1/a = \csc^{-1} 1\sqrt{1-a^2}$.

$\mathrm{Sin}^{-1} a \pm \sin^{-1} b = \sin^{-1}(a\sqrt{1-b^2} \pm b\sqrt{1-a^2})$.

$\mathrm{Cos}^{-1} a \pm \cos^{-1} b = \cos^{-1}(ab \pm \sqrt{(1-a^2)(1-b^2)})$.

$\mathrm{Tan}^{-1} a \pm \tan^{-1} b = \tan^{-1}[(a \pm b)/(1 \pm ab)]$.

16. SOLUTION OF PLANE TRIANGLES

A triangle has six parts, the sides a, b, c and angles A, B, C, angle A being opposite a, etc. Certain necessary relations exist between the parts, as that the sum of the angles $= 180°$, the sum of two sides is greater than the third side, and the greater side is opposite the greater angle. With these restrictions, a triangle can be determined when one side and two other parts are given.

Right Triangles

$\angle A + \angle B = 90°$; $\angle C = 90°$ (Fig. 29).

Given an angle and opposite side, as A, a.

$B = 90° - A$. $\quad c = a/\sin A$. $\quad b = a\cot A$.

Given an angle and adjacent side, as A, b.

$B = 90° - A$. $\quad a = b\tan A$. $\quad c = b/\cos A = b\sec A$.

Given two sides a, b.

$\tan A = a/b$. $\quad B = 90° - A$. $\quad c = \sqrt{a^2+b^2} = a/\sin A = a\csc A$.

Given a side, as a, and hypotenuse c.

$\sin A = a/c$. $\quad B = 90° - A$. $\quad b = \sqrt{(c+a)(c-a)}$.

Oblique Triangles

Sides a, b, c, angles A, B, C, angle A opposite side a, etc.

Law of sines: $a/\sin A = b/\sin B = c/\sin C$. (See also p. 24.)

Law of tangents: $(a+b)/(a-b) = \tan {}^1/_2(A+B)/\tan {}^1/_2(A-B)$.

Law of cosines:

$a^2 = b^2 + c^2 - 2bc\cos A$. $\quad b^2 = c^2 + a^2 - 2ca\cos B$.

$c^2 = a^2 + b^2 - 2ab\cos C$. $\quad \cos A = (b^2+c^2-a^2)/2bc$.

$\cos B = (c^2+a^2-b^2)/2ac$. $\quad \cos C = (a^2+b^2-c^2)/2ab$.

If $s = {}^1/_2(a+b+c)$ and $r = \sqrt{(s-a)(s-b)(s-c)/s}$,

$\sin {}^1/_2A = \sqrt{(s-b)(s-c)/bc}$, $\quad \cos {}^1/_2A = \sqrt{s(s-a)/bc}$,

$\tan {}^1/_2A = r/(s-a)$;

Area $= \sqrt{s(s-a)(s-b)(s-c)} = {}^1/_2bc\sin A = {}^1/_2a^2\sin B\sin C/\sin A$.

$\sin A = 2\,area/bc$. $\quad \sin B = 2\,area/ca$. $\quad \sin C = 2\,area/bc$.

Sides: $a = b\cos C + c\cos B$. $\quad b = \cos A + a\cos C$.

$c = a\cos B + b\cos A$.

Sum of sines: $\sin A + \sin B + \sin C = 4\cos {}^1/_2A\cos {}^1/_2B\cos {}^1/_2C$.

Sum of cosines: $\cos A + \cos B + \cos C = 4\sin {}^1/_2A\sin {}^1/_2B\sin {}^1/_2C + 1$.

Sum of tangents: $\tan A + \tan B + \tan C = \tan A\tan B\tan C$.

Squares of sines: $\sin^2 A + \sin^2 B + \sin^2 C = 2\cos A\cos B\cos C + 2$.

Products of cotangents: $\cot A\cot B + \cot B\cot C + \cot C\cot A = 1$.

Sines of twice the angles: $\sin 2A + \sin 2B + \sin 2C = 4\sin 2A\sin 2B\sin 2C$.

Solutions. If one side and two other parts (sides or angles) of a triangle are known, the preceding equations give a definite solution in all cases but one. Solution simply involves selection of formulas which, with the known data, can be set up as equations with one unknown, and solving. The INDETERMINATE CASE arises when two sides and the angle opposite the shorter are given, *e.g.*, a, b, A (Fig. 32). When $a < b$ and $> b \sin A$, there are two solutions, as indicated. If A is acute and $a < b \sin A$ there is no solution. In all other cases there is one solution only.

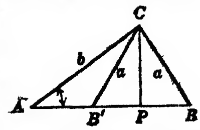

FIG. 32. Indeterminate triangle.

ANALYTIC GEOMETRY

Co-ordinates. For rectangular co-ordinates see Art. 3. OBLIQUE CO-ORDINATES are sometimes used, the axes forming an angle A not equal to 90°. The co-ordinates of a point are the lengths of lines drawn from the point to the axes parallel to respective axes.

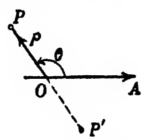

FIG. 33 Polar co-ordinates.

POLAR CO-ORDINATES of a point P in a plane (Fig. 33) are its distance OP from a fixed point O (the POLE), and the angle AOP between OP and a fixed line OA (POLAR AXIS). Distance OP is called the RADIUS VECTOR ρ of P; angle AOP is called the VECTORIAL ANGLE θ, which is positive or negative as in *Trigonometry* (Art. 15). The radius vector is positive when P lies on the terminal side of the vectorial angle, negative when on the terminal side produced through the pole. Equations in polar co-ordinates ρ and θ (POLAR EQUATIONS) are plotted by calculating corresponding values of ρ and θ, plotting the points, and drawing a smooth curve through them.

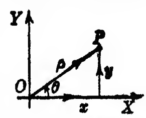

FIG. 34. Relation between rectangular and polar co-ordinates.

Relations between rectangular and polar co-ordinates of a point P (Fig. 34).

$$x = \rho \cos \theta, \; y = \rho \sin \theta. \qquad \rho = \pm\sqrt{x^2 + y^2}. \qquad \theta = \tan^{-1} y/x.$$

Transformation of rectangular co-ordinates. See Art. 19.

17. FORMULAS USING CO-ORDINATES

Length l of line joining two points.

Rectangular co-ordinates. (x_1, y_1) and (x_2, y_2): $l = \sqrt{(x_1 - x_2)^2 + (y_1 - y_2)^2}$.

Polar co-ordinates. (ρ_1, θ_1) and (ρ_2, θ_2): $l = \sqrt{\rho_1^2 + \rho_2^2 - 2\rho_1\rho_2 \cos(\theta_1 - \theta_2)}$.

Slope (m) of a line, produced, if necessary, to meet X-axis, is the tangent of the angle (INCLINATION, i) measured from the X-axis around to the line in a counterclockwise direction. Thus $m = \tan i$. The slope may have any value, positive or negative. Parallel lines have equal slopes. For two perpendicular lines, the slope of one is the negative reciprocal of the slope of the other. If (x_1, y_1) and (x_2, y_2) are points on a line, the slope is

$$m = (y_1 - y_2)/(x_1 - x_2).$$

Lines parallel to OX have slope zero, those parallel to OY have slope equal to infinity (Table 6).

Point of division. If $P_1(x_1, y_1)$, $P_2(x_2, y_2)$, $P(x, y)$ are three points on a line, then

$$x = (x_1 + rx_2)/(1 + r) \quad \text{and} \quad y = (y_1 + ry_2/(1 + r)$$

where r is numerically equal to the ratio of lengths P_1P and PP_2; r is positive when P is on segment P_1P_2, negative when outside.

Mid-point. Co-ordinates (x, y) of mid-point $(r = 1)$ are $^1/_2(x_1 + x_2)$, $^1/_2(y_1 + y_2)$.

Area of triangle with vertices (x_1, y_1), (x_2, y_2), (x_3, y_3) is

$$A = {}^1/_2(x_1y_2 - x_2y_1 + x_2y_3 - x_3y_2 + x_3y_1 - x_1y_3).$$

For any given numerical case write abscissae and ordinates in rows as indicated, repeating the first abscissa and ordinate. (1) Multiply each abscissa by the ordinate in the next column, and add the results. (2) Multiply each ordinate by the abscissa in next column and add results. (3) Subtract the last sum from the first sum and divide by 2.

$$\begin{matrix} x_1 x_2 x_3 x_1 \\ y_1 y_2 y_3 y_1 \end{matrix}$$

$$\text{By determinants (Art. 4).} \quad A = {}^1/_2 \begin{vmatrix} x_1 & y_1 & 1 \\ x_2 & y_2 & 1 \\ x_3 & y_3 & 1 \end{vmatrix}.$$

Area of any polygon with vertices given may be found in the same manner by writing down the co-ordinates of successive points on the perimeter as in the annexed scheme and following the rule just given.

$$\begin{matrix} x_1 x_2 \ldots x_n x_1 \\ y_1 y_2 \ldots y_n y_1 \end{matrix}$$

18. CURVES AND STANDARD EQUATIONS

Locus of an equation in two variables (usually x and y) representing rectangular co-ordinates is a curve (or group of curves) passing through all points whose co-ordinates satisfy that equation, and through such points only.

Symmetry. Curve is symmetric with respect to the X-axis, or to the Y-axis, or to the origin, when the given equality is unaffected by replacing y by $-y$, or x by $-x$, or x and y simultaneously by $-x$ and $-y$, respectively.

Equation of a curve in two variables is that equation satisfied by the co-ordinates of every point on the curve, and such that every point whose co-ordinates satisfy the equation lies on the curve.

Parametric equations of a curve arise when the co-ordinates x and y of a point on the curve are each expressed in terms of a third variable (called PARAMETER). Elimination of parameter gives the rectangular equation.

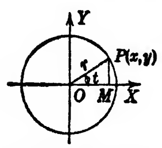

FIG. 35. Parameter of a circle.

Example 1. In the circle of Fig. 35, if $OP = r$, angle $MOP = t$, then $x = OM = r\cos t$, and $y = MP = r\sin t$, are parametric equations of the circle. Squaring and adding gives the rectangular equation $x^2 + y^2 = r^2$.

Example 2. Find the equation of the circle whose center is $C(-1, 2)$ and radius is 4.

Let $P(x, y)$ be any point on the circle (Fig. 36). Then $PC = 4$ by definition. But PC = length of line joining (x, y) and $(-1, 2) = \sqrt{(x+1)^2 + (y-2)^2}$ (Art. 17). Substitute this expression in $PC = 4$ to eliminate PC; square both sides, transpose and reduce. Result is $x^2 + y^2 + 2x - 4y - 11 = 0$, the required equation of the circle.

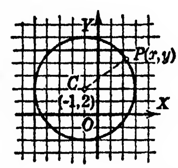

FIG. 36. Circle of known center and radius.

Points of intersection of two curves whose equations are given are those points whose co-ordinates satisfy both equations; they are found by solving the given equations. See Art. 4.

Straight Lines

Notation (Fig. 37). OA = intercept on X-axis = a. OB = intercept on Y-axis = b. ON = perpendicular distance from origin = p. Slope $m = \tan i$ (Art. 17). The angle that ON forms with OX, measured counterclockwise, = n. Let $P(x, y)$ be any point on the line.

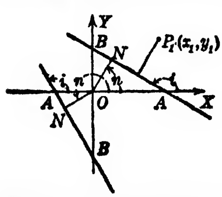

FIG. 37. Notation for linear equations.

Equations:

$y = mx + b$, given m and b.

$x/a + y/b = 1$, given a and b.

$y - y_1 = m(x - x_1)$, given one point (x_1, y_1) and m.

$(y - y_1)/(x - x_1) = (y_1 - y_2)/(x_1 - x_2)$, given two points (x_1, y_1), (x_2, y_2).

$x\cos n + y\sin n = p$, given p and n.

Line parallel to X-axis; $y = b$; parallel to Y-axis, $x = a$. Equation of X-axis, $y = 0$; of Y-axis, $x = 0$.

Polar equations. $P(\rho,\theta)$ any point on line, or circumference.

$\rho = p\cos(\theta - n)$, given n and p. $\rho(A\cos\theta + B\sin\theta) + C = 0$ is a straight line.

$\theta = a$ *constant* is equation of a line through pole.

General equation of first degree in x, y is $Ax + By + C = 0$. The locus is a straight line.

$m = \tan i = -A/B;$ $a = -C/A;$ $b = -C/B;$

$p = \pm C/\sqrt{A^2 + B^2};$ $n = \sin^{-1} B/\sqrt{A^2 + B^2} = \cos^{-1} A/\sqrt{A^2 + B^2}.$

In equation for p, choose the sign of the radical opposite to the sign of C.

Perpendicular distance d from line $Ax + By + C = 0$ to point $P_1(x_1, y_1)$.

$$d = (Ax_1) + (By_1 + C)/\sqrt{A^2 + B^2}.$$

If $C \neq 0$, and the radical is given the sign opposite to C, d is positive when P_1 and O are on opposite sides of the line, negative when on the same side.

Relations between two lines $A_1x + B_1y + C_1 = 0$ and $A_2x + B_2y + C_2 = 0$. The lines are PARALLEL if $A_1B_2 - A_2B_1 = 0$; they are PERPENDICULAR if $A_1A_2 + B_1B_2 = 0$. The ANGLE BETWEEN the lines $= \tan^{-1}(A_1B_2 - A_2B_1)/(A_1A_2 + B_1B_2)$.

Locus of an equation of higher degree in x and y is a group of straight lines when the equation can be written as the product of real factors of the first degree equal to zero. The locus consists of the lines obtained by setting the factors equal to zero.

Example. Equation $9x^2 - y^2 = 0$ may be written $(3x - y)(3x + y) = 0$. Locus is pair of intersecting lines $3x - y = 0$, $3x + y = 0$.

Circle

Notation. Center $C(a, b)$; radius $= r$; $P(x, y)$ = any point on the circumference.
Equations:

$(x - a)^2 + (y - b)^2 = r^2$, given radius r and center (a, b).
$x^2 + y^2 - 2ax = 0$, center $(a, 0)$ on X-axis; passes through origin.
$x^2 + y^2 - 2by = 0$, center $(0, b)$ on Y-axis; passes through origin.
$x^2 + y^2 = r^2$, center at origin.

$x^2 + y^2 + Dx + Ey + F = 0$ is a circle when $D^2 + E^2 - 4F$ is positive. Center is $(-\frac{1}{2}D, -\frac{1}{2}E)$, radius $= \frac{1}{2}\sqrt{D^2 + E^2 - 4F}$. The locus is a POINT CIRCLE when $r = 0$. The equation has no locus when $D^2 + E^2 - 4F < 0$.

Polar equations: $P(\rho, \theta)$ = any point on circumference.
$\rho = 2r \cos \theta$; center on polar axis, radius r, circle passes through the pole.
$\rho = 2r \sin \theta$; center $(r, 90°)$, radius r, circle passes through pole.
$\rho = r$, center at pole.
$\rho^2 + \rho(D \cos \theta + E \sin \theta) + F = 0$ is a circle.

Parabola

Definitions. A PARABOLA is a curve described by a point moving so that it remains always equidistant from a fixed point (FOCUS) and a fixed line (DIRECTRIX).

Notation (Fig. 38). Focus F, directrix DD', distance from focus to directrix $= p$. The line drawn through the focus perpendicular to the directrix is the AXIS of the curve. The curve is symmetric with respect to its axis. The point on the axis midway between focus and directrix is the VERTEX. The vertex lies on the parabola. The chord drawn through the focus parallel to the directrix is the LATUS RECTUM; length $= 2p$.

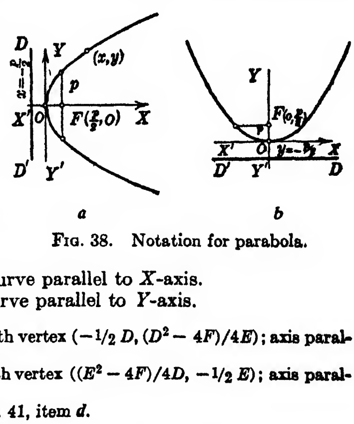

Fig. 38. Notation for parabola.

Equations, rectangular. $P(x, y)$ any point on curve.
$y^2 = 2px$; vertex at origin; axis of curve along X-axis; focus $(\frac{1}{2}p, 0)$; equation of directrix $x = -\frac{1}{2}p$. (Fig. 38, item *a*.)
$x^2 = 2py$; vertex at origin; axis of curve along Y-axis; focus $(0, \frac{1}{2}p)$; equation of directrix, $y = -\frac{1}{2}p$. (Fig. 38, item *b*.)
$(y - b)^2 = 2p(x - a)$; vertex (a, b), axis of curve parallel to X-axis.
$(x - a)^2 = 2p(y - b)$; vertex (a, b) axis of curve parallel to Y-axis.

$x^2 + Dx + Ey + F = 0$, E not zero, is a parabola with vertex $(-\frac{1}{2} D, (D^2 - 4F)/4E)$; axis parallel to Y-axis; latus rectum $= -E$.
$y^2 + Dx + Ey + F = 0$, D not zero, is a parabola with vertex $((E^2 - 4F)/4D, -\frac{1}{2} E)$; axis parallel to X-axis, latus rectum $= -D$.
Parabola with axis not parallel to XX' or YY', see Fig. 41, item *d*.

Polar equation. $\rho = p/(1 - \cos \theta)$; pole at focus, polar axis along axis of curve.
Tangent and normal (Fig. 39).

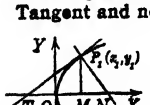

Fig. 39. Parabolic tangent and normal.

$y_1y = p(x + x_1)$ is the equation of the tangent to $y^2 = 2px$ at $P_1(x_1, y_1)$.
$y_1(x - x_1) + p(y - y_1) = 0$ is the equation of the normal P_1N.

SUBTANGENT ($= MT$) is bisected at the vertex ($TO = OM$). SUBNORMAL ($= MN$) is of constant length $= p$.

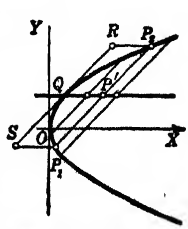

Fig. 40. Parabolic diameter.

A diameter is a line drawn parallel to the axis of a parabola (Fig. 40). The diameter bisects all chords parallel to the tangent at the point where the diameter meets the parabola. The distance of a diameter from the axis $= p/m$ where m = the slope of the

chords. The area of the parabolic segment P_1QP_2, cut off by any chord P_1P_2, $= {}^2/_3$ area of parallelogram P_1P_2RS.

Construction of parabola. Given focus F and directrix DD' (Fig. 41, item a). Draw axis MX. Bisect FM, giving vertex V. Through any point A to right of V draw AB parallel to DD'. From F as center with a radius equal to MA strike arcs to intersect AB at P and Q. Then P and Q are points on the curve. Any number of points may be constructed in this manner.

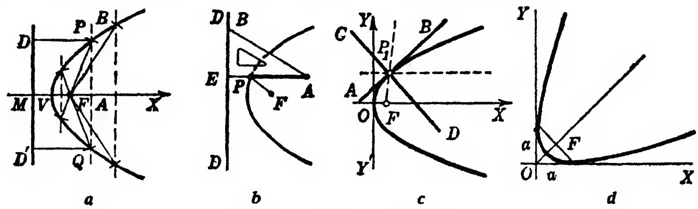

FIG. 41. Parabolic constructions.

Fig. 41, item b, shows how to trace a parabola by sliding a triangle ABE along DD; ends of string of length AE are fastened to A on triangle and F on paper; pencil is at P.

To construct a tangent at a given point P_1 (Fig. 39), draw P_1M through P_1 perpendicular to the axis OX, lay off $OT = OM$, draw TP_1, which is the tangent required. Line $y = mx + c$ is a tangent to $y^2 = 2px$ when $c = p/2m$. Two perpendicular tangents intersect on the directrix and the line joining the points of contact passes through the focus. The foot of the perpendicular drawn from the focus upon a tangent lies on the tangent drawn at the vertex. The tangent and normal bisect the angles formed by lines drawn through the point of contact and the focus and through the point of contact parallel to the axis. (Fig. 41, item c.) Two parabolas with common focus and axis (CONFOCAL PARABOLAS) and vertices upon opposite sides of the focus intersect at right angles. The equation $y^2 = 2px + p^2$ represents a system of confocal parabolas, p having any constant value. The equation of a parabola referred to the tangents drawn at the extremities of the latus rectum as axes is $\sqrt{x} + \sqrt{y} = \sqrt{a}$, where $a = p\sqrt{2}$. (Fig. 41, item d.)

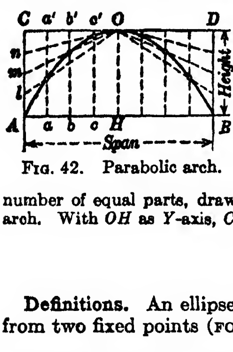

FIG. 42. Parabolic arch.

To construct a parabolic arch with given span ($2a$) **and height** (h) (Fig. 42). Draw rectangle $ABCD$, divide AC, AH, OC into the same number of equal parts, draw lines aa', bb', cc', On, Om, and Ol. The intersections are points on the arch. With OH as Y-axis, CD as X-axis, the equation of the parabola in Fig. 42 is $x^2 = a^2y/h$.

Ellipse

Definitions. An ellipse is described by a point moving so that the sum of its distances from two fixed points (FOCI) remains constant.

Notation (Fig. 43). Foci F, F'. $PF + PF' = 2a$. $FF' = 2c$. AA' = MAJOR AXIS $= 2a$. BB' = MINOR AXIS $= 2b$. $a > b$. VERTICES A, A' are the extremities of the major axis. CENTER, O. LATUS RECTUM is the chord drawn through the focus perpendicular to the major axis, length $= 2b^2/a$. ECCENTRICITY, $e = c/a$. $e < 1$. Lines DD, $D'D'$, (item b) drawn parallel to the minor axis, at distances $\pm a^2/c$ from the center, are DIRECTRICES. $PF = e \times PE$, $PF' = e \times PE'$. An ellipse is also a curve described by a point moving so that the ratio of its distances from a fixed point (focus) and fixed line (directrix) remains constant (eccentricity) and less than unity.

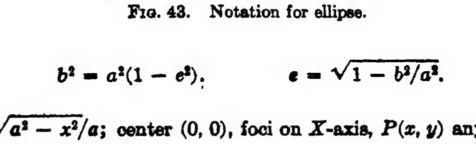

FIG. 43. Notation for ellipse.

Formulas:

$a^2 = b^2 + c^2$. $\quad c = ae$. $\quad b^2 = a^2(1 - e^2)$. $\quad e = \sqrt{1 - b^2/a^2}$.

Equations:

$x^2/a^2 + y^2/b^2 = 1$ or $y = \pm b\sqrt{a^2 - x^2}/a$; center (0, 0), foci on X-axis, $P(x, y)$ any point on curve.

$(x - h)^2/a^2 + (y - k)^2/b^2 = 1$, center (h, k), major axis parallel to X-axis.

Interchange a and b in the two preceding equations if the major axis is vertical.

$Ax^2 + By^2 + Dx + Ey + F = 0$, A and B positive numbers (not zero), is an ellipse when $R = {}^1/_4(D^2/A + E^2/B - 4F) > 0$. Center is $(-D/2A, -E/2B)$; semi-axes $(\sqrt{R/A}, \sqrt{R/B})$; major

axis is parallel to X-axis or Y-axis according as $A < B$ or $A > B$. For $A = B$, locus is a circle. For $R = 0$, locus reduces to point $(-D/2A, -E/2A)$, a POINT-ELLIPSE. The equation has no locus when $R < 0$.

For an ellipse with major axis oblique to the X-axis, see Art. 19.

Parametric equations. $x = a \cos \phi$, $y = b \sin \phi$, where ϕ = ECCENTRIC ANGLE of point $P(x, y)$, ($= \angle XOM$, item b).

Focal radii of $P(x, y$, item $b)$. $F'P = a + ex$, $FP = a - ex$.

Polar equation. $\rho = a(1 - e^2)/(1 - e \cos \theta)$; pole at left-hand focus, polar axis drawn through other focus (Item b). $F'P = \rho$, $\angle OF'P = \theta$.

Tangent and normal to ellipse $b^2x^2 + a^2y^2 = a^2b^2$.

$b^2x_1x + a^2y_1y = a^2b^2$ is the equation of the tangent at (x_1, y_1).

$a^2y_1x - b^2x_1y = (a^2 - b^2)x_1y_1$ is the equation of the normal through (x_1, y_1).

$y = mx + c$ is a tangent when $c = \pm\sqrt{a^2m^2 + b^2}$.

Diameter is a line drawn through the center. Tangents drawn at the extremities of a diameter are parallel. All chords parallel to these tangents are bisected by the diameter. In Fig. 44, AB and CD are CONJUGATE DIAMETERS, each being parallel to chords bisected by the other. If m, m' are slopes of the conjugate diameters, $mm' = -b^2/a^2$. The area of the circumscribed parallelogram $MNQP$ formed by tangents drawn at the extremities of conjugate diameters equals $4ab$. If $2a'$, $2b'$, are the lengths of AB, CD, then $a'^2 + b'^2 = a^2 + b^2$.

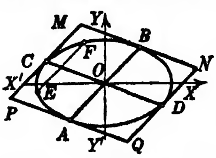

FIG. 44. Diameters of an ellipse.

Radii of curvature (Art. 21) for points A, B at extremities of the axes are determined (Fig. 45) by drawing a line from vertex D of the rectangle $ADBC$ perpendicular to the chord AB. Then M, N are centers of curvature for A, B, respectively, and AM, BN are radii of curvature. $AM = b^2/a$, $BN = a^2/b$.

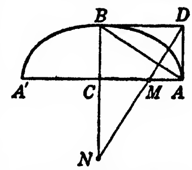

FIG. 45. Radii of curvature of an ellipse.

Construction of ellipse. When the major and minor axes AA', BB' are given, draw circles upon those lines as diameters (Fig. 46, item a) and from any point M on the larger circle draw radius OM, and draw SP and MR parallel to OA and OB, respectively, to intersect at P, on the ellipse. An ellipse is a flattened circle, in the sense that the ordinates of the large circle are reduced in the ratio $b : a$ to the given ordinates of the ellipse.

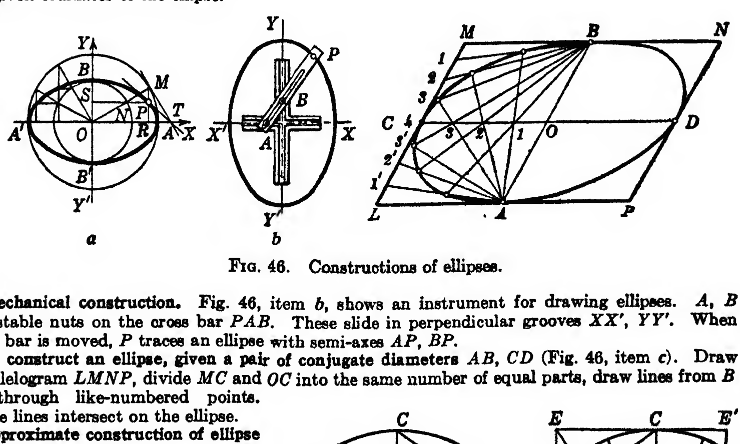

FIG. 46. Constructions of ellipses.

Mechanical construction. Fig. 46, item b, shows an instrument for drawing ellipses. A, B are adjustable nuts on the cross bar PAB. These slide in perpendicular grooves XX', YY'. When the cross bar is moved, P traces an ellipse with semi-axes AP, BP.

To construct an ellipse, given a pair of conjugate diameters AB, CD (Fig. 46, item c). Draw the parallelogram $LMNP$, divide MC and OC into the same number of equal parts, draw lines from B and A, through like-numbered points. These lines intersect on the ellipse.

Approximate construction of ellipse by circular arcs. *With four centers* (Fig. 47, item a):

Lay off $CF = OB - OC$, bisect BF at S, and draw SH perpendicular to BC. Set off $OG' = OG$ and $OH' = OH$. Then the four centers are G, H, G', H', and the radii are GB, HC, $G'A$, $H'D$.

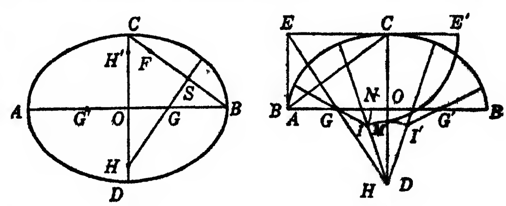

FIG. 47. Construction of approximate ellipse.

With eight centers (Fig. 47, item b): $OB = a$, $OC = b$. Draw EGH perpendicular to AC. Then G, H are centers with radii GA, HC (radii of curvature at A and C). Produce EC to E' making $CE' = OC$. Upon EE' as a diameter draw a circle cutting CD at M. Then $CM = \sqrt{ab}$, and is the third radius. (See Fig. 9, item b.) Lay off AN =

CM, and from G, H strike arcs with radii GN, HM, intersecting at I, the third center for the elliptic arc from A to C. Eight centers are necessary to complete the ellipse. Radius $AG = b^2/a$, $HC = a^2/b$, and the third radius CM is the mean proportional between AG and HC.

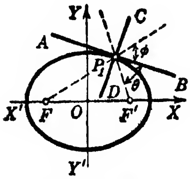

FIG. 48. Tangent and normal to ellipse.

To construct a tangent at P (Fig. 46, item a) extend ordinate RP to meet the outer circle at M and draw tangent MT; then TP is tangent to the ellipse. Two perpendicular tangents intersect on the circle $x^2 + y^2 = a^2 + b^2$ (DIRECTOR CIRCLE). The foot of the perpendicular from the focus to a tangent lies on the circle $x^2 + y^2 = a^2$. The tangent and normal bisect angles formed by focal radii through the point of contact (Fig. 48).

To draw tangents from an external point P (Fig. 49). Draw secants PQR, PST; chords QT, RS, intersecting at L, and secants QS, RT, intersecting at M. Then LM intersects the ellipse in points of contact A, B.

To construct an elliptic arch of given height (h) **and span** ($2s$) **with axes in a given ratio** (m) (Fig. 50). $GH = mh$, DF is diameter of the circle drawn through H. Lines BG, BC, DF are divided into the same number of equal parts and lines drawn to intersect on the ellipse as shown. Axes are $h + s^2/m^2h$ (along CD produced) and $mh + s^2/mh$.

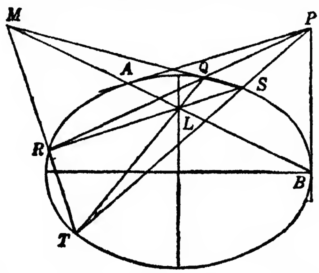

FIG. 49. Tangent from external point.

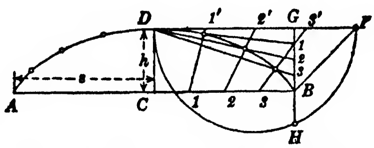

FIG. 50. Construction of elliptic arch.

Hyperbola

Definitions. A hyperbola is traced by a point moving so that the difference of its distances from two fixed points (FOCI) remains constant.

Notation (Fig. 51). Foci F, F'. $FF' = 2c$. $PF' - PF = 2a$. AA' = TRANSVERSE AXIS $= 2a$. BB' = CONJUGATE AXIS $= 2b$. VERTICES are A, A'. CENTER, is O. LATUS RECTUM is a chord drawn through the focus perpendicular to the transverse axis produced; length $= 2b^2/a$. ECCENTRICITY $e = c/a$. $e > 1$. Lines DD, $D'D'$ (Fig. 51, item c) drawn parallel to the conjugate axis at distances

FIG. 51. Notation for hyperbola.

$\pm a^2/c$ from the center are DIRECTRICES. $PF = e \times PE$, $P'F' = e \times P'E'$. The hyperbola is also traced by a point so moving that the ratio of its distances from a fixed point (FOCUS) and fixed line (DIRECTRIX) remain constant (ECCENTRICITY) and greater than unity.

Formulas.

$c^2 = a^2 + b^2$. $\quad c = ae$. $\quad b^2 = a^2(e^2 - 1)$. $\quad e = \sqrt{1 + b^2/a^2}$.

Equations:

$x^2/a^2 - y^2/b^2 = 1$ or $y = \pm b\sqrt{x^2 - a^2}/a$; center (0, 0); foci on X-axis, $P(x, y)$ any point on curve.

$(x - h)^2/a^2 - (y - k)^2/b^2 = 1$, center (h, k), traverse axis parallel to X-axis.

If the transverse axis is vertical, interchange x and y, and h and k, in the two preceding equations.

$Ax^2 - By^2 + Dx + Ey + F = 0$, A and B positive numbers (not zero), is a hyperbola when $R = 1/4\,(D^2/A - E^2/B - 4F)$ is not zero. Center is $(-D/2A, E/2B)$; semi-axes $\sqrt{|R/A|}$, $\sqrt{|R/B|}$

(absolute values); transverse axis is parallel to X-axis or Y-axis according as $R > 0$ or < 0. When $A = B$, the locus is a rectangular hyperbola. If $R = 0$, the locus is a pair of lines intersecting at $(-D/2A, E/2B)$, with slopes $\pm\sqrt{A/B}$.

$2Cxy + Dx + Ey + F = 0$, C not zero, is a rectangular hyperbola when $R = 1/4\,(DE - CF)/C^2$ is not zero. Center is $(-E/2C, -D/2C)$; $a^2 = |R|$; asymptotes are parallel to OX, OY. When $R = 0$, the locus is a pair of lines $x + E/2C = 0$, $y + D/2C = 0$. See also Art. 19.

Parametric equations. $x = a \cosh u$, $y = b \sinh u$. (For the meaning of u, see Art. 13.)

Focal radii of P are $F'P = ex + a$; $FP = ex - a$ (Fig. 51, item a).

Polar equation, $\rho = a(e^2 - 1)/(e \cos\theta - 1)$; pole at left-hand focus, polar axis drawn through other focus (Fig. 51, item a). $F'P = \rho$, $\angle XF'P = \theta$.

Conjugate hyperbolas have the property that the transverse and conjugate axes of one are respectively the conjugate and transverse axes of the others (Fig. 52). The equations differ only in the sign of the constant term and are $x^2/a^2 - y^2/b^2 = \pm 1$.

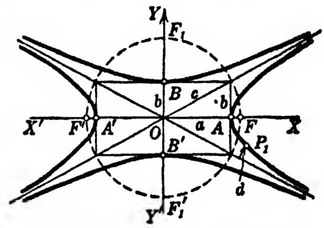

FIG. 52. Conjugate hyperbolas.

Asymptotes of $x^2/a^2 - y^2/b^2 = 1$ are the lines $x/a - y/b = 0$; $x/a + y/b = 0$. Conjugate hyperbolas have the same asymptotes. The diagonals of the rectangle in Fig. 52 lie on the asymptotes. The branches of the hyperbola approach infinitely near its asymptotes as they recede to infinity.

Rectangular hyperbola has equal axes ($a = b$), and asymptotes perpendicular. $e = \sqrt{2}$. The equation is, $x^2 - y^2 = a^2$; foci $(\pm a\sqrt{2}, 0)$. The equation referred to the asymptotes as axes is $2xy = \pm a^2$. A rectangular hyperbola is also called an EQUILATERAL HYPERBOLA.

Tangent and normal to $b^2x^2 - a^2y^2 = a^2b^2$.

$b^2x_1x - a^2y_1y = a^2b^2$, is the equation of the tangent at (x_1, y_1).

$a^2y_1x - b^2x_1y = (a^2 - b^2)x_1y_1$, is the normal through (x_1, y_1).

$y = mx + c$ is a tangent when $c = \pm\sqrt{a^2m^2 - b^2}$.

Diameter is a line drawn through the center, and intersects the hyperbola or conjugate hyperbola (asymptotes excluded). The tangents drawn at the extremities of a diameter are parallel. All chords parallel to these tangents terminating in a conjugate hyperbola are bisected by the diameter. In Fig. 53, AB, CD are conjugate diameters, each bisects chords parallel to the other. Product of slopes $= b^2/a^2$. The area of the parallelogram formed by tangents at A, B, C, $D = 4ab$. The vertices are on the asymptotes. $\overline{OB}^2 + \overline{OC}^2 = a^2 + b^2$.

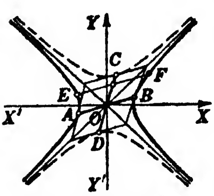

FIG. 53. Conjugate diameters.

Confocal ellipses and hyperbolas. An ellipse and a hyperbola with common foci intersect at right angles. The equation $x^2/(a^2 + k) + y^2/(b^2 + k) = 1$, for values of $k > -a^2$, represents a system of curves composed of confocal ellipses and hyperbolas. (Fig. 54; $a = 5$, $b = 3$.)

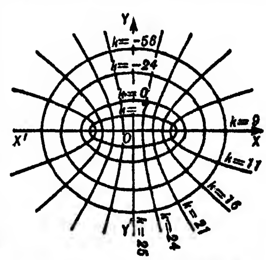

FIG. 54. Confocal ellipses and hyperbolas.

Construction of hyperbola. When foci F, F_1, and transverse axis AB are given, points on the curve may be constructed as in Fig. 55, item a. $FR = FJ$ = any radius $> AB$. $JE = AB$. $F_1R = FE = FJ - AB$.

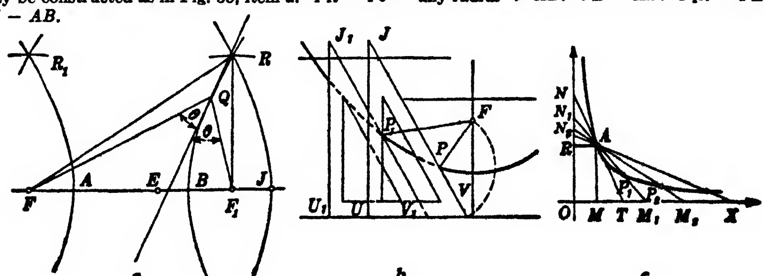

FIG. 55. Constructions of hyperbolas.

Mechanical construction. In Fig. 55, item b, focus and directrix are given. Triangle JUV is moved along the ruler edge (directrix), one end of a string of length JV is fastened at J, the other end at F (focus), and kept taut by a pencil point at P. $PF = PV$. Distance from P to the ruler $= PV \sin \angle UVJ = PF \sin \angle UVJ$. Hence eccentricity $= \csc \angle UVJ$.

When asymptotes OX, OY and one point A on the curve are given, construction is shown in Fig. 55, item c (which is drawn for a rectangular hyperbola): $AN_2 = M_2P_2$; $AN_1 = M_1P_1$, etc.

To construct a tangent at Q (Fig. 55, item a), draw FQ, F_1Q, and construct the bisector of the angle FQF_1. This is the desired tangent. Two perpendicular tangents intersect on the circle $x^2 + y^2 = a^2 - b^2$. (Impossible when $a < b$.) The foot of the perpendicular from the focus upon a tangent lies on circle $x^2 + y^2 = a^2$. Tangent and normal bisect angles formed by the focal radii through the point of contact. The portion of a tangent lying between its intersection with asymptotes is bisected at the point of contact, and forms with the asymptotes a triangle of constant area ab. Hence to draw a tangent at A (Fig. 55, item c) when the asymptotes are given, draw AM, AR, each parallel to an asymptote. Lay off $MT = OM$, $RN = OR$, and draw NT. This is the tangent required.

19. LOCUS PROBLEMS AND PARAMETRIC EQUATIONS

Transformation of rectangular co-ordinates. New axes of co-ordinates $O'X'$, $O'Y'$ are drawn through a new origin $O'(h, k)$. Co-ordinates of any point P are (x, y) referred to old axes and (x', y') referred to the new axes.

Translation. If the new axes are parallel to the original axes, $x = x' + h$; $y = y' + k$.

Translation and rotation. If the new axis $O'X'$ makes an angle θ with the original X-axis, $x = x' \cos\theta - y' \sin\theta + h$; $y = x' \sin\theta + y' \cos\theta + k$.

By these formulas a given equation can be transformed so that the new axes of co-ordinates assume any desired position. By suitable choice of h, k, and θ, reductions of equations to simpler forms may often be effected (see *post*).

General equation of the second degree; locus of $Ax^2 + 2Bxy + Cy^2 + 2Dx + 2Ey + F = 0$. By rotation of the axes of co-ordinates through the angle $\theta = \frac{1}{2} \tan^{-1} 2B/(A - C)$, the equation will assume a form in which the xy-term is lacking. Hence the locus comes under the cases already discussed. Tests are given in Table 8, excluding the case of no locus.

Table 8. Tests for curve of general equation of second degree

Test	General case	Exceptional case
$B^2 - AC = 0$	Parabola	Two parallel lines; one line
$B^2 - AC < 0$	Ellipse	Point ellipse
$B^2 - AC > 0$	Hyperbola	Two intersecting lines

Conic section is traced by a point moving so that the ratio (ECCENTRICITY) of its distance from a fixed point (FOCUS) and a fixed line (DIRECTRIX) is constant. POLAR EQUATION is $\rho = ep/(1 - e\cos\theta)$, pole at focus, polar axis perpendicular to directrix, distance of focus from directrix $= p$, eccentricity $= e$. A conic section is a parabola, ellipse, or hyperbola according as $e = 1$, $e < 1$, or $e > 1$. Plane sections of a right circular conical surface are conic sections, a parabola when the plane is parallel to an element, an ellipse when the plane cuts all elements, a hyperbola in other cases.

Parametric equations. It is often easier to express the rectangular co-ordinates x, y of a moving point P in terms of a parameter (parametric equations of the locus of P, Art. 18) than to derive the rectangular equation directly. Study of the problem will determine the choice of parameter.

Example. A rigid isosceles right-triangular frame moves so that the extremities of one side move on perpendicular lines. Find the curve traced by the third vertex.

Solution. In Fig. 56, choose $\angle ABO = \theta$ for a parameter. The side AB of the triangle $= a$. Then $x = OB + BM = AB \cos\theta + BP \cos(90° - \theta)$, $y = MP = BP \sin(90° - \theta)$. Hence $x = a(\cos\theta + \sin\theta)$, $y = a\cos\theta$. The rectangular equation is $x^2 - 2xy + 2y^2 = a^2$, and the locus is an ellipse. (See Table 8.)

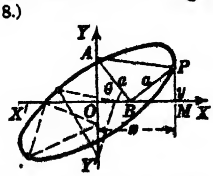

FIG. 56. Parametric construction of an ellipse.

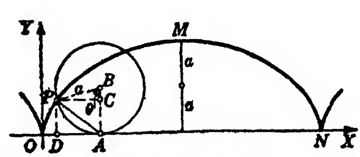

FIG. 57. Cycloid.

Cycloid is traced by a point P on the circumference of a circle which rolls without slipping on a straight line. Parametric equations (Fig. 57) are $x = a(\theta - \sin\theta)$, $y = a(1 - \cos\theta)$, θ in radians; rectangular equation is $x = a \operatorname{vers}^{-1} y/a - \sqrt{2ay - y^2}$.

Construction (Fig. 58) makes $M_1D_1 = CC_1$, $M_2D_2 = CC_2$, $M_3D_3 = CC_3$, etc. NORMAL at P passes through A (Fig. 57). A point Q on the radius BP, or the radius produced, describes a PROLATE CYCLOID if Q is inside of the rolling circle and a CURTATE CYCLOID if Q is outside. The equations of such a cycloid are $x = a\theta - b \sin \theta$, $y = a - b \cos \theta$ when $b = BQ$.

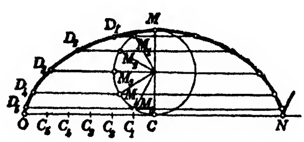

FIG. 58. Construction of cycloid.

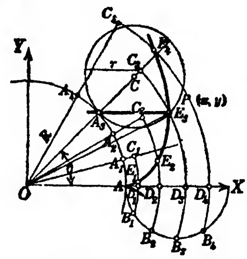

FIG. 59. Epicycloid.

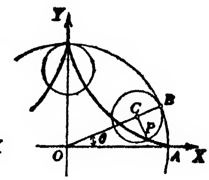

FIG. 60. Hypocycloid.

Epicycloid (or **hypocycloid**) is traced by a point on the circumference of a circle which rolls without slipping on the outside (or inside) of a fixed circle. If radius of fixed circle $= R$, radius of rolling circle $= r$, parametric equations are: EPICYCLOID (Fig. 59).

$$x = (R + r) \cos \theta - r \cos (\theta + R\theta/r),$$
$$y = (R + r) \sin \theta - r \sin (\theta + R\theta/r).$$

HYPOCYCLOID (Fig. 60) is the same, with the sign of r changed. Parameter θ = the angle described by the line of centers measured from a position when the tracing point is on the fixed circle. The normal to the curve for any position of the tracing point passes through the point of contact of the circles. (E_3A_3, Fig. 59.)

Construction of epicycloid (Fig. 59). Arcs AA_1, AA_2, etc., on the fixed circle equal arcs AB_1, AB_2, etc., on the rolling circle. Arcs B_1C_1, B_2C_2, etc., are drawn with O as center and $D_1B_1 = C_1E_1$, $D_2B_2 = C_2E_2$, etc. A similar construction holds for the hypocycloid.

Epitrochoid (or **Hypotrochoid**) is the curve traced by a point (Fig. 59 or 60) on the radius of the rolling circle at a fixed distance b from its center. The parametric equations of the curve are

$$x = (R + r) \cos \theta - b \cos (\theta + R\theta/r),$$
$$y = (R + r) \sin \theta - b \sin (\theta + R\theta/r).$$

For a hypotrochoid, change signs of r and b. If $R = 2r$, the hypocycloid is a diameter of the fixed circle, and the hypotrochoid is an ellipse. If $R = 4r$, the hypocycloid has four cusps and is called the ASTROID (Fig. 61). Its rectangular equation is $x^{2/3} + y^{2/3} = R^{2/3}$. If $R = 2r$, the epicycloid is the CARDIOID. (Fig. 62.) When each chord drawn

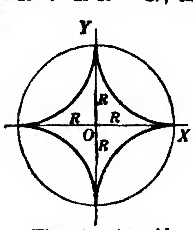

Fig. 61. Astroid.

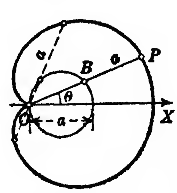

Fig. 62. Cardioid.

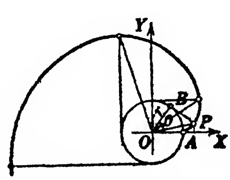

FIG. 63. Involute of a circle.

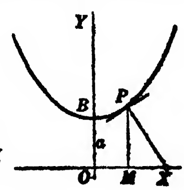

Fig. 64. Catenary.

from a fixed point of a circle is produced a distance equal to the diameter, the extremities will lie on a cardioid. Polar equation of the cardioid is $\rho = a(1 + \cos \theta)$; rectangular equation is $(x^2 + y^2 - ax)^2 = a^2(x^2 + y^2)$.

Involute of a circle (Fig. 63) is traced by the end of a taut string wrapped around a fixed circle and unwinding. Parametric equations are

$$x = r \cos \theta + r\theta \sin \theta; \qquad y = r \sin \theta - r\theta \cos \theta \quad (\theta \text{ in radians}).$$

At any instant the portion of string unwound (as BP) is normal to the involute and tangent to the circle, and BP = *arc* AB.

Catenary (Fig. 64) is the curve assumed by a flexible cord of uniform density when suspended at its extremities. Its equation is $y = a \cosh (x/a)$. (Table 27, Sec. 22.) The constant a equals the ratio of the horizontal component of tension in the cord to the

weight of cord per unit length. The length of the normal drawn from $p(x, y)$ on the curve and intercepted by $OX = y^2/a$.

Spiral of Archimedes (Fig. 65) is traced by a point moving with constant speed v on a line which turns about a fixed point on itself with uniform angular velocity w. Polar equation is $\rho = a\theta$ (θ in radians), where $a = v/w$, w being expressed in radians per sec., or $\rho = b\theta/360°$ (θ in degrees, $b = 2\pi a$).

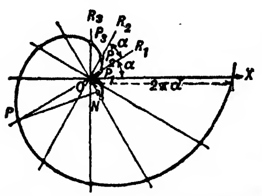

FIG. 65. Spiral of Archimedes.

Construction. Draw radial lines OR_1, OR_2, OR_3, etc., forming angles α, 2α, 3α, etc., with OX; lay off $OP_1 = a\alpha$ (α in radians) $= b\alpha/360$ (α in degrees), $OP_2 = 2OP_1$, $OP_3 = 3OP_1$, etc. Consecutive coils of the spiral intercept equal lengths ($2\pi a$) on any radius. The normal at any point P cuts off a constant distance a from O on a line ON drawn perpendicular to OP.

Logarithmic spiral (Fig. 66) is a curve cutting all radii drawn to it from a fixed point at the same angle. The polar equation is $\rho = be^{a\theta}$ (θ in radians). The cotangent of the angle between radius OP_1 and the tangent at P_1 equals a. The radius equals b when $\theta = 0$. If P_1 and P_2 are points on the curve, and angle P_1OP_2 is bisected and OP_3 is laid off on this bisector equal to the mean proportional between OP_1 and OP_2 ($OP_3 = \sqrt{OP_1 \cdot OP_2}$), then P_3 is on the curve. For negative values of θ increasing numerically, the spiral winds about O with decreasing radius.

To construct a normal at P, lay off on OP from P a length equal to 1, at this point erect a perpendicular to OP of length a, then the normal passes through the end of this perpendicular.

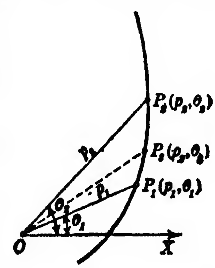

FIG. 66. Logarithmic spiral.

A helix is the path of a point which moves on a right circular cylinder of radius r at constant speed v parallel to the axis and at the same time rotates about the axis with uniform angular velocity w (radians per sec.). The curve cuts all elements at an angle A whose tangent equals rw/v. Consecutive coils intercept equal lengths h ($= 2\pi r \cot A$) on an element. The length of a helix for one complete turn equals $2\pi r/\sin A$. The curve formed by a screw thread is a helix, and h = the pitch of the thread.

CALCULUS

Definitions. When two variables x and y are so related that the value of y depends on the value of x, then y is said to be a FUNCTION of x, written $y = f(x)$. x is the INDEPENDENT VARIABLE, y the DEPENDENT variable. If $x = x_0$ gives a corresponding value of $y = y_0$, then $y_0 = f(x_0)$. A mathematical expression containing a variable is a FUNCTION of this variable.

From $y = \log_e x$, it follows that $x = e^y$ (Art. 5). Functions $\log_e x$ and e^y are called INVERSE FUNCTIONS.

An INCREMENT of a variable is an increase (+) or a decrease (−) in its value. Increment of x is denoted by Δx, of y by Δy; etc. When values of the independent variable (x) and its increment (Δx) are given, the increment of dependent variable $y = f(x)$ is $\Delta y = f(x + \Delta x) - f(x)$; that is, Δy is the difference of the values of the function for the two values ($x + \Delta x$ and x) of the independent variable.

Example. If $y = 2 \sin x$, the increment of y when $x = 30°$ and $\Delta x = 2°$ is $\Delta y = 2 \sin 32° - 2 \sin 30° = 2(0.5299 - 0.5000) = 0.060$.

The RATIO OF CORRESPONDING INCREMENTS $\Delta y/\Delta x$ is the slope of the secant drawn through points on the graph of the function with co-ordinates (x, y) $(x + \Delta x, y + \Delta y)$. Thus, in Fig. 67, $\Delta y/\Delta x = RQ/PR = \tan \angle RPQ$ = the slope of the secant line PS through $P(x, y)$ and $Q(x + \Delta x, y + \Delta y)$.

20. DERIVATIVES

Derivative of a function (dy/dx) is obtained by calculating the ratio of corresponding increments of the function and the independent variable and finding the LIMITING VALUE

of this ratio when the increment of the independent variable decreases numerically and becomes zero.

Slope of tangent at a point on the graph of $y = f(x)$ is given immediately by the derivative of the function; that is, the value of the derivative for a given value of x equals the tangent of the angle formed with the X-axis by the line drawn tangent to the graph at the corresponding point.

In Fig. 67 when $\Delta x = 0$, the point Q takes successive positions on the arc PQ nearer P, the secant PS turns about P, and, eventually, when Δx becomes zero, secant PS becomes tangent to the graph at P, its slope becoming, in the limit, the slope of PT.

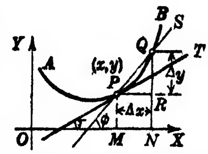

FIG. 67. Ratio of corresponding increments.

Table 9. Derivatives

[c, n are constants, e the Napierian base (Art. 5), and u, v, w are functions of x.]

(1) $\dfrac{dc}{dx} = 0.$

(2) $\dfrac{dx}{dx} = 1.$

(3) $\dfrac{d}{dx}(u + v - w) = \dfrac{du}{dx} + \dfrac{dv}{dx} - \dfrac{dw}{dx}.$

(4) $\dfrac{d}{dx}(cv) = c\dfrac{dv}{dx}.$

(5) $\dfrac{d}{dx}(uv) = u\dfrac{dv}{dx} + v\dfrac{du}{dx}.$

(6) $\dfrac{d}{dx}(v)^n = n(v)^{n-1}\dfrac{dv}{dx}.$

(7) $\dfrac{d}{dx}\left(\dfrac{u}{v}\right) = \dfrac{1}{v^2}\left(v\dfrac{du}{dx} - u\dfrac{dv}{dx}\right).$

(8) $\dfrac{d}{dx}\log_e v = \dfrac{1}{v}\dfrac{dv}{dx}.$

(9) $\dfrac{d}{dx}\log_{10} v = \dfrac{\log_{10} e}{v}\dfrac{dv}{dx}.$

(10) $\dfrac{d}{dx}e^v = e^v\dfrac{dv}{dx}.$

(11) $\dfrac{d}{dx}c^v = c^v \log_e c\dfrac{dv}{dx}.$

(12)* $\dfrac{d}{dx}\sin v = \cos v\dfrac{dv}{dx}.$

(13)* $\dfrac{d}{dx}\cos v = -\sin v\dfrac{dv}{dx}.$

(14)* $\dfrac{d}{dx}\tan v = \sec^2 v\dfrac{dv}{dx}.$

(15)* $\dfrac{d}{dx}\cot v = -\csc^2 v\dfrac{dv}{dx}.$

(16)* $\dfrac{d}{dx}\sec v = \sec v \tan v\dfrac{dv}{dx}.$

(17)* $\dfrac{d}{dx}\csc v = -\csc v \cot v\dfrac{dv}{dx}.$

(18) $\dfrac{d}{dx}\sin^{-1} v = \dfrac{1}{\sqrt{1 - v^2}}\dfrac{dv}{dx}.$

(19) $\dfrac{d}{dx}\cos^{-1} v = -\dfrac{1}{\sqrt{1 - v^2}}\dfrac{dv}{dx}.$

(20) $\dfrac{d}{dx}\tan^{-1} v = \dfrac{1}{1 + v^2}\dfrac{dv}{dx}.$

(21) $\dfrac{d}{dx}\cot^{-1} v = -\dfrac{1}{1 + v^2}\dfrac{dv}{dx}.$

(22) $\dfrac{d}{dx}\sec^{-1} v = \dfrac{1}{v\sqrt{v^2 - 1}}\dfrac{dv}{dx}.$

(23) $\dfrac{d}{dx}\csc^{-1} v = -\dfrac{1}{v\sqrt{v^2 - 1}}\dfrac{dv}{dx}.$

(24) $\dfrac{d}{dx}\sinh v = \cosh v\dfrac{dv}{dx}.$

(25) $\dfrac{d}{dx}\cosh v = \sinh v\dfrac{dv}{dx}.$

(26) $\dfrac{d}{dx}\tanh v = \operatorname{sech}^2 v\dfrac{dv}{dx}.$

(27) $\dfrac{d}{dx}\coth^2 v = -\operatorname{csch}^2 v\dfrac{dv}{dx}.$

(28) $\dfrac{d}{dx}\operatorname{sech} v = -\operatorname{sech} v \tanh v\dfrac{dv}{dx}.$

(29) $\dfrac{d}{dx}\operatorname{csch} v = -\operatorname{csch} v \coth v\dfrac{dv}{dx}.$

(30) $\dfrac{d}{dx}\sinh^{-1} v = \dfrac{1}{\sqrt{v^2 + 1}}\dfrac{dv}{dx}.$

(31) $\dfrac{d}{dx}\cosh^{-1} v = \dfrac{1}{\sqrt{v^2 - 1}}\dfrac{dv}{dx}.$

(32) $\dfrac{dv}{dx} = \dfrac{dv}{dt}\cdot\dfrac{dt}{dx}.$

(33) $\dfrac{dv}{dx} = 1\Big/\dfrac{dx}{dv}.$

* In 12–17, v must be measured in radians.

Differentiation of a function is accomplished by applying in succession formulas from Table 9.

Examples. (1) Find $\dfrac{d}{dx}3\sqrt{9 + x^2}$. Apply (4) with $c = 3$, $v = \sqrt{9 + x^2}$; the result is $3\dfrac{d}{dx}\sqrt{9 + x^2}$. Change the square root to the power $1/2$ and apply (6) with $v = 9 + x^2$, $n = 1/2$. This gives $3 \times$

$\frac{1}{2}(9 + x^2)^{-\frac{1}{2}}\frac{d}{dx}(9 + x^2)$. Now apply (3). $\frac{d}{dx}(9 + x^2) = \frac{d}{dx}9 + \frac{d}{dx}x^2$. By (1) $\frac{d}{dx}9 = 0$, and by (6) and (2) $\frac{d}{dx}x^2 = 2x$. The final result is $3x(9 + x^2)^{-\frac{1}{2}}$, or $3x/\sqrt{9 + x^2}$.

(2) Find $\frac{d}{dx}(25 \cos x - 12.8 \cot x)$. Applying (3), $\frac{d}{dx}(25 \cos x) - \frac{d}{dx}(12.8 \cot x)$. Apply (5) in each term and then (13) and (15). The result is $-25 \sin x + 12.8 \csc^2 x$.

Logarithmic differentiation is a method under which the derivative of the Nap log of a function is worked out and this result multiplied by the function, the final product being the derivative of the latter.

Example. Find $\frac{d}{dx}\frac{x}{\sqrt{9 - x^2}}$. $\text{Log}_e \frac{x}{\sqrt{9 - x^2}} = \log_e x - \frac{1}{2}\log_e(9 - x^2)$ (see Art. 1). Differentiating this by (3), (4), (8), successively, the result is $\frac{1}{x} + \frac{x}{9 - x^2} = \frac{9}{x(9 - x^2)}$. Multiplying this by $\frac{x}{\sqrt{9 - x^2}}$, the product is $9/(9 - x^2)^{\frac{3}{2}}$.

21. APPLICATIONS OF DIFFERENTIAL CALCULUS

Maximum and minimum values of a function. In Fig. 68, which is a graph of $f(x)$, the value of $f(x)$ for $x = OM$ is MA; this value of $f(x)$ is a MAXIMUM, *i.e.*, greater than the values of the function immediately preceding or following it. Similarly, the function has a MINIMUM ($= NB$) when $x = ON$. The slope of the graph is zero at A and also at B (horizontal tangents). Passing along the graph through A from left to right, the slope changes sign from $+$ to $-$, whereas at B, the slope changes sign from $-$ to $+$. Hence $f(x)$ is a maximum for $x = a$ when its derivative vanishes for $x = a$ and changes sign from $+$ to $-$ as x increases through a; $f(x)$ is a minimum for $x = a$ when its derivative vanishes for $x = a$ and changes sign from $-$ to $+$ as x increases through a.

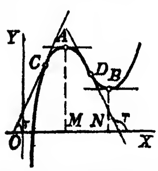

FIG. 68. Maximum and minimum.

To examine a function for maximum or minimum values, find its derivative, set it equal to zero, and solve this equation for values (CRITICAL VALUES) of the variable. Consider one critical value at a time and determine the sign of the derivative, first for a value of the variable a trifle less than the critical value, and second for a value a trifle greater. Change in sign from $+$ to $-$ shows a maximum value of the function for the particular critical value, of $-$ to $+$, a minimum value.

In many problems the function to be examined must be derived, and it is often advisable to graph this function. The conditions of the problem usually determine without testing whether the function is a maximum or a minimum.

Examples. (1) An opening is to be dug from a point A to a point B, 300 ft. lower than A and 500 ft. east of A. On level A the opening is through earth, below A through solid rock. The cost through earth is \$1 per linear ft., through rock \$3 per linear ft. Find the distance tunneled on level A for least cost, and find the least cost.

In Fig. 69 the distances are marked in hundred feet. The cost of a tunnel from A to P is $100(5 - x)$ dollars, and of the incline from P to B is $100 \times PB \times 3 = 300\sqrt{9 + x^2}$ dollars. Hence the total cost is $100\,[5 - x + 3\sqrt{9 + x^2}]$ dollars. Fig. 70 shows the graph of this function. For minimum cost the derivative must vanish, hence $\frac{d}{dx}[5 - x + \sqrt{9 + x^2}] = 0$. The result (see Ex. 1, Art. 20) is $-1 + 3x/\sqrt{9 + x^2} = 0$, or $\sqrt{9 + x^2} = 3x$. Squaring and solving for x, $x = \sqrt{9/8} = 3\sqrt{2}/4 = 1.06$. Hence the length of the tunnel section is $500 - 106 = 394$ ft. The length of the inclined part through rock is $\sqrt{9 + 9/8} = 3.18$ hundred feet. The minimum cost is $394 + 954 = \$1{,}348$.

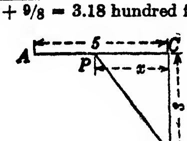

FIG. 69. Sketch of excavation.

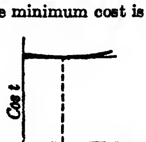

FIG. 70. Cost of excavation.

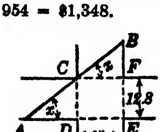

FIG. 71. Sketch for Ex. 2.

(2) A girder 25 ft. long is moved on rollers along a passageway 12.8 ft. wide and thence into a corridor at right angles to the passageway. Neglecting the width of the girder, how wide must the corridor be?

In Fig. 71, $w = AE - AD = AB \cos x - CD \cot x$, or $w = 25 \cos x - 12.8 \cot x$. When the girder just swings clear, w is a maximum, hence $dw/dx = 0$. This gives (by Ex. 2, Art. 20) $-25 \sin x$

$+ 12.8 \csc^2 x = 0$. From Art. 15, $\csc x = 1/\sin x$, hence $\sin^3 x = 12.8/25 = 64/125$. Then $\sin x = 4/5$, and $\cos x = 3/5$, $\cot x = 3/4$, $w = 25(3/5) - 12.8(3/4) = 15 - 9.6 = 5.4$ ft.

Derivatives of higher order arise when the first derivative is differentiated, this result differentiated, etc. The order of a derivative is indicated by the number of times the original function is differentiated. A second derivative is the derivative of the first derivative. The notation is $\frac{d}{dx}\left(\frac{dy}{dx}\right) = \frac{d^2y}{dx^2}$ (SECOND DERIVATIVE); d^3y/dx^3, d^4y/dx^4, . . ., d^ny/dx^n, third, fourth, . . ., nth, derivative, respectively. For $f(x)$, successive derivatives are indicated by placing an accent on the f, as $f'(x)$, $f''(x)$, $f'''(x)$, $f^{IV}(x)$ . . . $f^{(n)}(x)$.

Sign of second derivative for a given value of x determines whether the graph is concave downward (a maximum as at A, Fig. 68) or concave upward (a minimum as at B). If positive, it is a minimum; if negative, a maximum. This is a convenient test when the second derivative can be calculated readily.

Differential of a function is the product of its derivative by the increment of the independent variable. $d[f(x)] = f'(x)\Delta x$. Then $d(x) = 1 \times \Delta x$ (written $dx = \Delta x$). Also $dy = dy/dx$ times dx. The differential and the increment of an independent variable are identical, but the differential and increment of a function are not. In Fig. 72, when passing from P to P', $\Delta x = MM' = PQ = dx$, increment of function $y = f(x)$ is QP', but the differential of the function is QT, that is, the differential of the function is the increment of the ordinate of the tangent to the graph at the point under consideration. Differentials are INFINITESIMALS, *i.e.*, variables whose numerical values decrease and ultimately become zero. The preceding definitions give the derivative equal to the quotient of corresponding differentials dy and dx (a DIFFERENTIAL QUOTIENT). The differential of a function is the principal part of its increment. The ratio of the increment to the differential becomes unity when the increment of the variable becomes zero. In problems involving infinitesimals, the increment of a function is replaced by its differential. This principle of replacing the increment by its differential has wide application in calculus. More generally, one infinitesimal may be replaced by another if the limit of their ratio is unity.

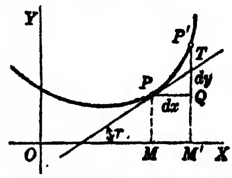

FIG. 72. Differential.

Example. Find the differential of the arc of a curve. Passing from P to Q along the curve (Fig. 73), the increment of arc is arc $PQ = \Delta s$. The chord $PQ = \sqrt{(\Delta x)^2 + (\Delta y)^2}$. When $\Delta x = 0$, the ratio of arc PQ to chord PQ becomes unity. Hence chord PQ may be replaced by Δs, this by ds, and Δx and Δy by dx and dy, respectively. Hence $ds = \sqrt{dx^2 + dy^2}$.

Differential of arc s of a curve. In rectangular co-ordinates, $ds = \sqrt{dx^2 + dy^2} = \sqrt{1 + (dy/dx)^2}\,dx = \sqrt{1 + (dx/dy)^2}\,dy$. In polar co-ordinates $ds = \sqrt{d\rho^2 + \rho^2 d\theta^2} = \sqrt{\rho^2 + (d\rho/d\theta)^2}\,d\theta$.

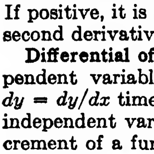

FIG. 73. Differential of PQ.

Small errors. If an error h is made in measuring x, the corresponding error in calculating $f(x)$ is $f(x + h) - f(x)$ = increment of $f(x)$. When h is numerically small, the increment of the function may be replaced by its differential, that is, *error in* $f(x) = f'(x)$ *times error in* x. This formula determines the degree of approximation in value of a function when the degree of accuracy of the measurement of the variable is known.

Example. An angle x is measured as 45° with a possible error of $\pm 1'$. What is the corresponding error in $\tan x$? *Solution.* The error in $\tan x = \frac{d}{dx}(\tan x)$ times the error in x (in radians) $= \sec^2 x$ times *error in* x. $1' = 0.000291$ rad. (see Table 15, Sec. 22). $\sec^2 45° = 2$. Hence the required error is ± 0.000582 unit, that is, $\tan x$ lies between 0.999 and 1.001, using three decimal places.

Probable error of $y = f(x)$ is $f'(x)$ *times the probable error in* x. (Art. 11.)

Partial derivatives. A function of several independent variables $x, y, z, \ldots$ is represented by $f(x, y, z, \ldots)$. Derivatives may be formed by varying one variable only, and are called PARTIAL DERIVATIVES. NOTATION: $\delta f/\delta x$, $\delta f/\delta y$, $\delta f/\delta z$, etc., or $D_x f$, $D_y f$, $D_z f$, etc. The TOTAL DIFFERENTIAL is $df = \frac{\delta f}{\delta x}dx + \frac{\delta f}{\delta y}dy + \frac{\delta f}{\delta z}dz + \ldots$

When the independent variables receive increments dx, dy, dz, etc., the PRINCIPAL PART of the increment of the function is df. When $x, y, z \ldots$ are functions of the same variable t, the TOTAL DERIVATIVE of f with respect to t is

$$\frac{df}{dt} = \frac{\delta f}{\delta x}\frac{dx}{dt} + \frac{\delta f}{\delta y}\frac{dy}{dt} + \frac{\delta f}{\delta z}\frac{dz}{dt} + \ldots$$

This formula gives the rate of change of a function in terms of the rates of change of the independent variables.

Small errors. When the value of a function is determined by measurement of several variables $x, y, z, \ldots$ with small errors $dx, dy, dz, \ldots$, the corresponding error df in the function is given by the above formula for total differential df.

Example. Two sides x, y of a triangle are 81.25 in., 91.04 in., respectively, with possible errors ± 0.01 in. in each. The included angle C is 30° with a possible error of 1′. Find the maximum error possible in the area.

Solution. Area $= u = \frac{1}{2}xy \sin C$ (Art. 13). Form du by the above formula. Then $du = \frac{1}{2}y \sin C\,dx + \frac{1}{2}x \sin C\,dy + \frac{1}{2}xy \cos C\,dC$. Substitute $x = 81.25$, $y = 91.04$, $dx = dy = 0.01$, $\sin C = 0.5$, $\cos C = 0.8660$, $dC = 0.0002909$ (radians in 1′). Result is $du = 1.36$ sq. in. The area computed by the given values is 1,850 sq. in.

Percentage error is the relative error du/u(d Nap log u) times 100.

In the above example, $du/u = dx/x + dy/y + \cot C\,dC$, that is, the relative error in area equals the sum of the relative errors in measurements of the sides x and y increased by the relative error in $\sin C$. (See Art. 1.) With the same absolute error in reading the angle C, the relative error in the value of $\sin C$ decreases as C increases. For the values given, $du/u = 0.000735$. Hence the percentage error is $\frac{7}{100}$ of 1%.

Probable error e of a function $f(x, y, z, \ldots)$ in terms of the probable errors $e_1, e_2, e_3 \ldots$ of measured quantities x, y, z, is given by formula

$$e = \sqrt{(\delta f/\delta x)^2 e_1^2 + (\delta f/\delta y)^2 e_2^2 + (\delta f/\delta z)^2 e_3^2 + \ldots}$$

Rates. In Fig. 72 rate of change of y along the tangent PT per unit change in x is constant and equals numerically the slope of the tangent. But the rate of change of the function at P (instantaneous rate) per unit change in x is the same as the rate of change at y along the tangent at P. This gives an interpretation of dy/dx as a rate, namely, rate of change in y per unit change in x.

Examples. (1) The velocity of a point moving along a line at a distance x from a fixed point on that line is dx/dt (variable t representing time), since VELOCITY is the rate of change of distance per unit change in time (time-rate of change of distance). ACCELERATION $= dv/dt$, the time-rate of change of velocity.

(2) Sand pouring from a chute at the rate of 50 cu. ft. per min. forms a conical pile with base diameter always equal to height. How rapidly is the height of the pile increasing when it is 10 ft. high?

Volume of pile $= V = \frac{1}{3}\pi x \cdot x^2/4 = \pi x^3/12$, when x = diameter = height. Differentiating with respect to t, $dV/dt = \pi/12 \times 3x^2 dx/dt$. But dV/dt = time-rate of change of volume = 50 cu. ft. per min., and $x = 10$ ft. Also dx/dt is the rate at which the height of the pile is increasing per unit time. This is the unknown sought. Solving, $dx/dt = 4\dfrac{dV}{dt}/\pi x^2 = 200/100\pi = 0.64$ ft. per min.

Curvature of a curve is the rate at which a point describing the curve changes direction of motion. CURVATURE AT A POINT is the rate of change of the angle which the tangent forms with a fixed line per unit arc on the curve (arc-rate of change of direction). In Fig. 74 the tangent turns through angle Δi as P moves to P', a distance Δs along the curve. The curvature at $P = di/ds$. Angle i is measured in radians, and curvature is therefore expressed in radians per unit length of arc. The CURVATURE OF A CIRCLE is the same at all points and equals the reciprocal of the radius, numerically. CIRCLE OF CURVATURE (Fig. 75) at point P on a curve is the circle tangent at P whose curvature equals that of the curve at P. The center of this circle is the CENTER OF CURVATURE of the curve. The circle of curvature crosses the curve at the point of contact.

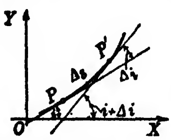

FIG. 74. Curvature.

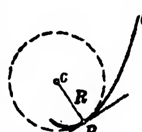

FIG. 75. Circle of curvature.

Formulas for curvature

Rectangular co-ordinates. K = curvature, R = radius of curvature, (a, b) = center of curvature, $p = dy/dx$, $q = d^2y/dx^2$.

$$K = q/(1 + p^2)^{3/2}. \qquad R = 1/K. \qquad a = x - p(1 + p^2)/q. \qquad b = y + (1 + p^2)/q.$$

Polar co-ordinates. $s = d\rho/d\theta$, $t = d^2\rho/d\theta^2$.

$$K = (\rho^2 - t\rho + 2s^2)/(\rho^2 + s^2)^{3/2}. \qquad R = 1/K.$$

The point of intersection of normals drawn at consecutive points $P(x, y)$ and $Q(x + \Delta x, y + \Delta y)$ approaches the center of curvature at P when Q moves along the curve toward P.

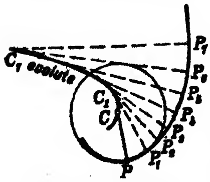

FIG. 76. Evolute.

Evolute of a curve (Fig. 76) is the locus of the centers of curvature of that curve. To find the equation of the evolute from the rectangular equation of the curve, work out expressions for a and b by the formulas given above, and eliminate x and y from these equations by means of the equation of the given curve.

Table 10. Radii of curvature (R) and evolutes for standard curves

Parabola ($y^2 = 2px$).
$R = (p + 2x)^{3/2}/\sqrt{p} = (p^2 + y^2)^{3/2}/p^2$ at (x, y).
Evolute $27py^2 = 8(x - p)^3$.

Ellipse ($b^2x^2 + a^2y^2 = a^2b^2$).
$R = (b^4x^2 + a^4y^2)^{3/2}/a^4b^4$ at (x, y).
Evolute $(ax)^{2/3} + (by)^{2/3} = (a^2 - b^2)^{2/3}$.

Hyperbola ($b^2x^2 - a^2y^2 = a^2b^2$).
$R = (b^4x^2 + a^4y^2)^{3/2}/a^4b^4$ at (x, y).
Evolute $(ax)^{2/3} - (by)^{2/3} = (a^2 + b^2)^{2/3}$.

Rectangular hyperbola ($2xy = a^2$).
$R = (x^2 + y^2)^{3/2}/a^2$ at (x, y).
Evolute $(x + y)^{2/3} - (x - y)^{2/3} = 2a^{2/3}$.

Cycloid (equations, Art. 19).
$R = 4a \sin \theta/2 = 2AP$ (Fig. 57).
Evolute $x = a(\theta' - \sin \theta')$; $y = a(1 - \cos \theta')$; $(\theta' = \theta + \pi)$, an equal cycloid.

Epicycloid (equations, Art. 19).
$R = 4(R' + r)r \sin (R'\theta/2r)/(R' + 2r)$. ($R'$ = the radius of the fixed circle.)

Hypocycloid (equations, Art. 19).
$R = 4(R' - r)r \sin (R'\theta/2r)/(R' - 2r)$. ($R'$ = the radius of the fixed circle.)

Catenary (Art. 19), ($y = a \cosh x/a$).
$R = y^2/a$, at any point (x, y).

Spiral of Archimedes (Art. 19), ($\rho = a\theta$ [θ in radians]).
$R = (\rho^2 + a^2)^{3/2}/(\rho^2 + 2a^2)$.

Logarithmic spiral (Art. 19), ($\rho = be^{a\theta}$).
$R = \rho\sqrt{1 + a^2}$.

Properties of an evolute. The normal to a given curve is tangent to the evolute at the corresponding center of curvature. The length of the arc of the evolute between two centers of curvature equals the difference of radii of the circles of curvature of the given curve having these centers.

In Fig. 76, arc C_1C_7 on the evolute = radius C_7P_7 − radius C_1P_1.

Curves having a given curve as a common evolute are called INVOLUTES of that curve. (Also called PARALLEL CURVES.)

Fig. 77 shows three involutes with a common evolute. If a flexible string is made to take the form of the evolute, and the free end is unwound and kept taut, this end will move along an involute.

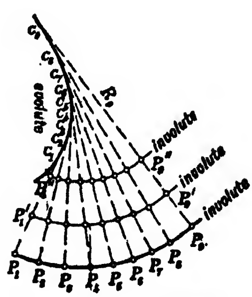

FIG. 77. Involutes.

22. SERIES

Definitions. A POWER SERIES consists of an indicated sum of terms each of which is the product of a constant and a positive integral power of a variable, arranged according to ascending powers of the variable, the number of terms being unlimited (INFINITE SERIES); thus: $1 + {}^1/_2x + {}^1/_3x^2 + {}^1/_4x^3 + \ldots$ *ad infinitum*. For a given value of the variable, the sum S_n of n (any number of) terms is a function of n. If, as n increases indefinitely, S_n remains finite and approaches a definite value S, that is, if $\lim_{n=\infty} S_n = S$, then the series is said to be CONVERGENT for this value of the variable and to have a sum equal to S. A power series which is convergent for values of the variable within a certain interval is called a CONVERGENT SERIES. A power series convergent for no value of the variable is called DIVERGENT.

Expansion of a function in a power series is accomplished by various formulas.

Taylor's series. Powers of $(x - a)$, where a is a given value of x.

$$f(x) = f(a) + f'(a)(x - a) + f''(a)\frac{(x - a)^2}{1\cdot 2} + f'''(a)\frac{(x - a)^3}{1\cdot 2\cdot 3} + \ldots + f^n(a)\frac{(x - a)^n}{n!} + \ldots$$

Expansion of a function as a polynomial of nth degree with a remainder is given by Taylor's Series, using first $(n + 1)$ terms and adding the REMAINDER TERM, $f^{(n+1)}(z)x^{n+1}/(n + 1)!$, where the value of z lies between a and x. This polynomial gives an approximate representation of the function for those values of x for which the remainder term is numerically less than the limit of error determined by the problem in hand.

Maclaurin's series. Powers of x.

$$f(x) = f(o) + f'(o)x + f''(o)\frac{x^2}{1\cdot 2} + f'''(o)\frac{x^3}{1\cdot 2\cdot 3} + \cdots + f^{(n)}(o)\frac{x^n}{n!} + \cdots.$$

Such expansions are valid only for values of x for which the series is convergent. Determination of the interval of convergence of a given series is a necessary precaution before using it instead of the function in numerical calculations (see Table 11).

Alternating series have the characteristic that successive terms have opposite signs. Such a series converges if successive terms decrease in numerical value and tend toward a limit zero. The sum is then less than the first term.

Table 11. Convergent power series

No.	Series	Interval of convergence
1	$(1+x)^{-1/2} = 1 - {}^1\!/_2\, x + \frac{1\cdot 3}{2\cdot 4}x^2 - \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}x^3 + \cdots$	$x^2 < 1$
2	$(a+bx)^{-1} = \frac{1}{a}\left(1 - \frac{bx}{a} + \frac{b^2x^2}{a^2} - \frac{b^3x^3}{a^3} + \cdots\right)$	$b^2x^2 < a^2$
3	$(1+x)^n = 1 + nx + \frac{n(n-1)}{2!}x^2 + \frac{n(n-1)(n-2)}{3!}x^3 + \cdots$	$x^2 < 1$
4	$e^x = 1 + x + \frac{x^2}{2!} + \frac{x^3}{3!} + \cdots + \frac{x^n}{n!} + \cdots$	All values of x
5	$\sin x = x - \frac{x^3}{3!} + \frac{x^5}{5!} - \frac{x^7}{7!} + \cdots$	All values of x
6	$\cos x = 1 - \frac{x^2}{2!} + \frac{x^4}{4!} - \frac{x^6}{6!} + \cdots$	All values of x
7	$\tan x = x + \frac{x^3}{3} + \frac{2}{15}x^5 + \frac{17}{315}x^7 + \cdots$	$x^2 < {}^1\!/_4\,\pi^2$
8	$\log_e x = 2\left(\frac{x-1}{x+1} + \frac{1}{3}\left(\frac{x-1}{x+1}\right)^3 + \frac{1}{5}\left(\frac{x-1}{x+1}\right)^5 + \cdots\right)$	$x > 0$
9	$\sec x = 1 + \frac{x^2}{2!} + \frac{5x^4}{4!} + \frac{61x^6}{6!} + \cdots$	$x^2 < {}^1\!/_4\,\pi^2$
10	$\sin^{-1} x = x + \frac{1}{6}x^3 + \frac{1\cdot 3}{2\cdot 4}\frac{x^5}{5} + \frac{1\cdot 3\cdot 5}{2\cdot 4\cdot 6}\frac{x^7}{7} + \cdots$	$x^2 < 1$
11	$\tan^{-1} x = x - {}^1\!/_3\, x^3 + {}^1\!/_5\, x^5 - {}^1\!/_7\, x^7 + \cdots$	$x^2 < 1$
12	$\sinh x = x + \frac{x^3}{3!} + \frac{x^5}{5!} + \frac{x^7}{7!} + \cdots$	All values of x
13	$\cosh x = 1 + \frac{x^2}{2!} + \frac{x^4}{4!} + \frac{x^6}{6!} + \cdots$	All values of x

Approximate formula for a function results when the function is set equal to a finite number of terms of its expansion in a convergent series. Such a formula holds with a certain degree of exactness for values of the variable for which the series is convergent. If the series is alternating, the error is less than the term in the series following the last term in the formula used.

Example. $1/\sqrt{1+x} = 1 - {}^1\!/_2\, x$ for $x^2 < 1$. The error is numerically less than $3x^2/8$. This result follows directly from Table 11, item 1.

Computation by series is often a useful means of calculation when tables are not at hand, or when the degree of approximation desired exceeds that given in tables or obtainable by logarithms which are accessible.

Example. Calculate $(34)^{1/5}$ to four decimal places. The nearest fifth power to 34 is $32 = 2^5$. Write the required quantity $(32 + 2)^{1/5} = (32(1 + 1/16))^{1/5} = (32)^{1/5}(1 + 1/16)^{1/5} = 4(1 + 1/16)^{1/5}$. Now $(1 + x)^{1/5} = 1 + 2x/5 - 3x^2/25 + 8x^3/125 - 26x^4/625 +$ etc. (Table 11, item 3). Put $x = 1/16$. Then $(34)^{1/5} = 4 + 0.1 - 0.001875 + 0.0000625 - 0.000003 + \ldots$ Taking four terms, the result is 4.0981875 and the error is less than the fifth term 0.000003. Hence 4.09818 is correct to five decimal places. (See Table 8, Sec. 22.)

23. INTEGRATION

Definitions. INTEGRATION is the process of finding a function of which a given function is the derivative, hence it is the inverse of differentiation. The sign of integration is $\int$, read "*integral of*." The process is indicated by writing the integral sign before the given function multiplied by the differential of the variable.

Example. $\int 6x dx = 3x^2$, since $\frac{d}{dx}(3x^2) = 6x$. Also $\int 6x dx = 3x^2 + C$, where C is any constant (CONSTANT OF INTEGRATION).

Integration is accomplished by reference to a Table of Integrals. The given integral is compared with one of similar form in the table, and, if necessary, made identical with this by simple substitutions. The examples given below illustrate the method.

Table 12. Integrals *

General forms

(1) $\int d[f(x)]\, dx = f(x)$.

(2) $\int cf(x)dx = c\int f(x)dx$, where c is a constant.

(3) $\int (u + v)dx = \int udx + \int vdx$.

(4) $\int udv = uv - \int vdu$.

Remark. Formula 4, "integration by parts" is very useful. It may be written

$$\int h(x)d[f(x)] = h(x)f(x) - \int f(x)d[h(x)].$$

The integral remaining in the right-hand member may often be found in tables when the original integral is not. In applying the formula, the given integrand is to be factored into the product of a function $h(x)$ by the differential of another function $f(x)$.

Integrals involving $a + bx$

(5) $\int (a + bx)^n dx = \frac{(a + bx)^{n+1}}{b(n + 1)}$, unless $n = -1$, then use 6.

(6) $\int \frac{dx}{a + bx} = \frac{1}{b}$ Nap log $(a + bx)$.

(7) $\int \frac{xdx}{a + bx} = \frac{1}{b^2}[a + bx - a \text{ Nap log } (a + bx)]$.

(8) $\int \frac{x^2dx}{a + bx} = \frac{1}{b^3}[1/2\,(a + bx)^2 - 2a(a + bx) + a^2 \text{ Nap log } (a + bx)]$.

(9) $\int \frac{dx}{x(a + bx)} = -\frac{1}{a} \text{ Nap log } \frac{a + bx}{x}$.

(10) $\int \frac{xdx}{(a + bx)^2} = \frac{1}{b^2}\left[\text{Nap log } (a + bx) + \frac{a}{a + bx}\right]$.

(11) $\int \frac{x^2dx}{(a + bx)^2} = \frac{1}{b^3}\left[a + bx - 2a \text{ Nap log } (a + bx) - \frac{a^2}{a + bx}\right]$.

* The constant of integration C should be added to the right-hand member in every formula. a, b, c, m, n, p, are constants.

(12) $\int x\sqrt{a+bx}\,dx = -\frac{2(2a-3bx)\sqrt{(a+bx)^3}}{15b^2}.$

(13) $\int \frac{dx}{x\sqrt{a+bx}} = \frac{1}{\sqrt{a}} \text{ Nap log } \frac{\sqrt{a+bx}-\sqrt{a}}{\sqrt{a+bx}+\sqrt{a}}$, for $a > 0$.

(14) $\int \frac{dx}{x\sqrt{a+bx}} = \frac{2}{\sqrt{-a}} \tan^{-1}\sqrt{\frac{a+bx}{-a}}$, for $a < 0$.

(15) $\int \frac{x\,dx}{\sqrt{a+bx}} = -\frac{2(2a-bx)}{3b^2}\sqrt{a+bx}.$

(16) $\int \frac{\sqrt{a+bx}\,dx}{x} = 2\sqrt{a+bx} + a\int \frac{dx}{x\sqrt{a+bx}}.$

(17) $\int \frac{x^n dx}{\sqrt{a+bx}} = \frac{2x^n\sqrt{a+bx}}{b(2n+1)} - \frac{2an}{b(2n+1)}\int \frac{x^{n-1}dx}{\sqrt{a+bx}}.$

(18) $\int \frac{dx}{x^n\sqrt{a+bx}} = -\frac{\sqrt{a+bx}}{(n-1)ax^{n-1}} - \frac{(2n-3)b}{2(n-1)a}\int \frac{dx}{x^{n-1}\sqrt{a+bx}}$, unless $n = -1$, then see 13, 14.

Integrals involving $a^2 - x^2$, or $x^2 - a^2$, or $x^2 + a^2$

(19) $\int \frac{dx}{a^2 - b^2x^2} = \frac{1}{2ab} \text{ Nap log } \frac{a+bx}{a-bx}.$

(20) $\int \frac{dx}{a^2 + b^2x^2} = \frac{1}{ab} \tan^{-1}\frac{bx}{a}.$

(21) $\int \frac{dx}{\sqrt{a^2-x^2}} = \sin^{-1}\frac{x}{a}.$

(22) $\int \frac{dx}{\sqrt{x^2 \pm a^2}} = \text{Nap log } (x + \sqrt{x^2 \pm a^2}).$

(23) $\int \frac{dx}{\sqrt{x^2+a^2}} = \sinh^{-1}\frac{x}{a}.$

(24) $\int \frac{dx}{\sqrt{x^2-a^2}} = \cosh^{-1}\frac{x}{a}.$

(25) $\int x(a+bx^2)^p dx = \frac{(a+bx^2)^{p+1}}{2b(p+1)}$, unless $p = -1$, then use 26.

(26) $\int \frac{x\,dx}{a+bx^2} = \frac{1}{2b} \text{ Nap log } (a+bx^2).$

(27) $\int \sqrt{a^2-x^2}\,dx = {}^1/_2\, x\sqrt{a^2-x^2} + {}^1/_2\, a^2 \sin^{-1}\frac{x}{a}.$

(28) $\int \sqrt{x^2 \pm a^2}\,dx = {}^1/_2\, x\sqrt{x^2 \pm a^2} \pm {}^1/_2\, a^2 \text{ Nap log } (x + \sqrt{x^2 \pm a^2}).$

(29) $\int \frac{dx}{x\sqrt{x^2-a^2}} = \frac{1}{a}\cos^{-1}\frac{a}{x}.$

(30) $\int \frac{dx}{x\sqrt{a^2 \pm x^2}} = -\frac{1}{a} \text{ Nap log } \left(\frac{a+\sqrt{a^2 \pm x^2}}{x}\right).$

(31) $\int \frac{\sqrt{a^2 \pm x^2}\,dx}{x} = \sqrt{a^2 \pm x^2} - a \text{ Nap log } \left(\frac{a+\sqrt{a^2 \pm x^2}}{x}\right).$

(32) $\int \frac{\sqrt{x^2-a^2}\,dx}{x} = \sqrt{x^2-a^2} - a\cos^{-1}\frac{a}{x}.$

(33) $\int \frac{\sqrt{a^2-x^2}}{x^2}\,dx = -\frac{\sqrt{a^2-x^2}}{x} - \sin^{-1}\frac{x}{a}.$

(34) $\int \frac{\sqrt{x^2 \pm a^2}}{x^2} dx = -\frac{\sqrt{x^2 \pm a^2}}{x} + \text{Nap log}\,(x + \sqrt{x^2 \pm a^2}).$

(35) $\int \frac{x^m dx}{(a^2 - x^2)^{1/2}} = -\frac{x^{m-1}}{m}\sqrt{a^2 - x^2} + \frac{(m-1)a^2}{m}\int \frac{x^{m-2}}{(a^2 - x^2)^{1/2}} dx.$

(36) $\int \frac{x^m dx}{\sqrt{x^2 \pm a^2}} = \frac{x^{m-1}}{m}\sqrt{x^2 \pm a^2} \mp \frac{a^2(m-1)}{m}\int \frac{x^{m-2}dx}{\sqrt{x^2 \pm a^2}}.$

Integrals involving $a + bx + cx^2$

(37) $\int \frac{dx}{a + bx + cx^2} = \frac{2}{\sqrt{4ac - b^2}} \tan^{-1} \frac{2cx + b}{\sqrt{4ac - b^2}}$, when $b^2 < 4ac$.

(38) $\int \frac{dx}{a + bx + cx^2} = \frac{1}{\sqrt{b^2 - 4ac}} \text{Nap log} \frac{2cx + b - \sqrt{b^2 - 4ac}}{2cx + b + \sqrt{b^2 - 4ac}}$, when $b^2 > 4ac$.

(39) $\int \frac{dx}{\sqrt{a + bx - cx^2}} = \frac{1}{\sqrt{c}} \sin^{-1} \frac{2cx - b}{\sqrt{b^2 + 4ac}}.$

(40) $\int \frac{dx}{\sqrt{a + bx + cx^2}} = \frac{1}{\sqrt{c}} \text{Nap log}\,(2cx + b + 2\sqrt{c}\sqrt{a + bx + cx^2}).$

(41) $\int \frac{x\,dx}{a + bx + cx^2} = \frac{1}{2c} \text{Nap log}\,(a + bx + cx^2) - \frac{b}{2c}\int \frac{dx}{a + bx + cx^2}.$

(42) $\int \frac{x\,dx}{\sqrt{a + bx + cx^2}} = \frac{1}{c}\sqrt{a + bx + cx^2} - \frac{b}{2c}\int \frac{dx}{\sqrt{a + bx + cx^2}}.$

Other algebraic integrals

(43) $\int x^{n-1}(a + bx^n)^p dx = \frac{(a + bx^n)^{p+1}}{bn(p+1)}$, unless $p = -1$, then use 44.

(44) $\int \frac{x^{n-1}dx}{a + bx^n} = \frac{1}{nb} \text{Nap log}\,(a + bx^n).$

Integrals involving transcendental functions

(45) $\int e^{ax}dx = e^{ax}/a.$

(46) $\int a^{nx}dx = a^{nx}/n \text{ Nap log } a.$

(47) $\int \text{Nap log } nx\, dx = x\,(\text{Nap log } nx - 1).$

(48) $\int \sin ax\, dx = -\cos ax/a.$

(49) $\int \cos ax\, dx = \sin ax/a.$

(50) $\int \tan ax\, dx = \text{Nap log sec } ax/a.$

(51) $\int \cot ax\, dx = \text{Nap log sin } ax/a.$

(52) $\int \sec ax\, dx = \text{Nap log}\,(\sec ax + \tan ax)/a.$

(53) $\int \csc ax\, dx = \text{Nap log}\,(\csc ax - \cot ax)/a.$

(54) $\int \sin^2 ax\, dx = \left(\frac{a}{2}x - \frac{1}{4}\sin 2ax\right)/a.$

(55) $\int \cos^2 ax\, dx = \left(\frac{ax}{2} + \frac{1}{4}\sin 2ax\right)/a.$

(56) $\int \tan^2 ax\, dx = \tan ax/a - x.$

(57) $\int \cot^2 ax\, dx = -\cot ax/a - x.$

(58) $\int \sec^2 ax\, dx = \tan ax/a.$

(59) $\int \csc^2 ax\, dx = -\cot ax/a.$

(60) $\int \sec ax \tan ax\, dx = \sec ax/a.$

(61) $\int \csc ax \cot ax\, dx = -\csc ax/a.$

(62) $\int (\sin x)^n dx = -\frac{(\sin x)^{n-1}\cos x}{n} + \frac{n-1}{n}\int (\sin x)^{n-2} dx.$

(63) $\int (\cos x)^n\, dx = \frac{(\cos x)^{-1}\sin x}{n} + \frac{n-1}{n}\int (\cos x)^{n-2}\, dx.$

(64) $\int (\sin x)^n \cos x\, dx = \frac{(\sin x)^{n-1}}{n+1}.$

(65) $\int (\cos x)^n \sin x\, dx = -\frac{(\cos x)^{n+1}}{n+1}.$

(66) $\int (\tan x)^n\, dx = \frac{(\tan x)^{n-1}}{n-1} - \int (\tan x)^{n-2}\, dx.$

(67) $\int (\cot x)^n\, dx = -\frac{(\cot x)^{n-1}}{n-1} - \int (\cot x)^{n-2}\, dx.$

(68) $\int xe^{ax}dx = \frac{e^{ax}}{a^2}(ax-1).$

(69) $\int x^n e^{ax}dx = \frac{x^n e^{ax}}{a} - \frac{n}{a}\int x^{n-1}e^{ax}dx.$

(70) $\int x^n \text{ Nap log } x\, dx = x^{n+1}\left[\frac{\text{Nap log } x}{n+1} - \frac{1}{(n+1)^2}\right].$

(71) $\int x^m \sin x\, dx = -x^m \cos x + m\int x^{m-1}\cos x\, dx.$

(72) $\int x^m \cos x\, dx = x^m \sin x - m\int x^{m-1}\sin x\, dx.$

(73) $\int e^{ax}\sin nx\, dx = \frac{e^{ax}(a \sin nx - n\cos nx)}{a^2+n^2}.$

(74) $\int e^{ax}\cos nx\, dx = \frac{e^{ax}(n \sin nx + a\cos nx)}{a^2+n^2}.$

(75) $\int \sin^{-1} x\, dx = x\sin^{-1} x + \sqrt{1-x^2}.$

(76) $\int \cos^{-1} x\, dx = x\cos^{-1} x - \sqrt{1-x^2}.$

(77) $\int \tan^{-1} x\, dx = x\tan^{-1} x - 1/2 \text{ Nap log } (1+x^2).$

(78) $\int \sec^{-1} x\, dx = x\sec^{-1} x - \text{Nap log } (x+\sqrt{x^2-1}).$

(79) $\int \sinh x\, dx = \cosh x.$

(80) $\int \cosh x\, dx = \sinh x.$

(81) $\int \tanh x\, dx = \text{Nap log} \cosh x.$

(82) $\int \coth x\, dx = \text{Nap log} \sinh x.$

For a more extended table, see B. O. Peirce, *A short table of integrals*, Ginn & Company, Boston, Mass.

Use of Table

(1) Work out $\int \sqrt{9-4x^2}\, dx.$

Since $\sqrt{9-4x^2} = 2\sqrt{(3/2)^2 - x^2}$, then $\int \sqrt{9-4x^2}\, dx = \int 2\sqrt{(3/2)^2 - x^2}\, dx = 2\int \sqrt{(3/2)^2 - x^2}\, dx$, by (2). The integral remaining is now in the form (27), with $a = 3/2$. $\therefore \int \sqrt{9-4x^2}\, dx = x\sqrt{(3/2)^2 - x^2} + (3/2)^2 \sin^{-1} 2x/3 + C.$

(2) Work out $\int x \sin 2x \, dx$.

This resembles formula 71. Put $v = 2x$, or $x = 1/2\, v$. Hence $dx = 1/2\, dv$. Then $\int x \sin 2x\, dx = \int 1/2\, v \sin v \; 1/2\, dv = 1/4 \int v \sin v\, dv$, by (2). The remaining integral is now (71), with $m = 1$. Using this and then putting $v = 2x$, the result is $1/4 \sin 2x - 1/2\, x \cos 2x + C$.

(3) Work out $\int \frac{x^2 dx}{4 - x^2}$.

This example illustrates cases where the division indicated in the integral can be performed. For $x^2/(4 - x^2) = -1 + 4/(4 - x^2)$.

$$\therefore \int \frac{x^2 dx}{4 - x^2} = -\int dx + 4\int \frac{dx}{4 - x^2} = -x + \text{Nap} \log \frac{2 + x}{2 - x} + C.$$

As a rule, in a quotient of two polynomials, divide numerator by denominator when the latter is of lower degree than the former or of the same degree.

Constant of integration. Integration by tables gives INDEFINITE INTEGRALS. Two indefinite integrals of a function differ by a constant. The CONSTANT OF INTEGRATION appearing in an indefinite integral takes on a definite value when the data of the problem are given properly.

Example. The slope of a certain curve at any point (x, y) is $-3x/2y$, and the curve passes through (4, 6). Find the equation of curve.

By Art. 20, the slope $= dy/dx$. Hence $dy/dx = -3x/2y$, from which the differential equation $2ydy = -3xdx$ results. Integrating both members, $y^2 = -3x^2/2 + C$, when C is to be determined so that the curve passes through (4, 6). Putting $x = 4$, $y = 6$, then $36 = -24 + C$, hence $C = 60$. The required equation is $y^2 = -3x^2/2 + 60$, or $3x^2 + 2y^2 - 120 = 0$, an ellipse.

Definite integral. Integrating between limits (DEFINITE INTEGRAL) consists in evaluating an indefinite integral for two values of variable x, say $x = b$, and $x = a$, and subtracting the results. The constant of integration then disappears. The notation follows: If $\int f(x)dx = F(x) + C$, then $\int_a^b f(x)dx = F(b) - F(a)$. b is the UPPER LIMIT; a the LOWER LIMIT. Interchanging the limits changes the sign of the definite integral.

24. APPLICATIONS OF INTEGRAL CALCULUS

Areas. Area between the curve $y = f(x)$, the X-axis, and the ordinates at $x = a$, $x = b$ (Fig. 78), such as area $CDPFE$, is given by the definite integral

$$Area = \int_a^b y\, dx, \text{ when } y = f(x).$$

Area swept over by radius vector ρ of a curve, $\rho = f(\theta)$, turning from $\theta = \alpha$ to $\theta = \beta$ is

$$Area = 1/2 \int_\alpha^\beta \rho^2 d\theta, \text{ when } \rho = f(\theta).$$

Area of surface of revolution. (x, y) is a point on the meridian section.

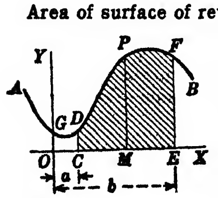

FIG. 78. Area under curve.

$$S = 2\pi \int y\, ds, \quad \text{or} \quad S = 2\pi \int x\, ds$$

according to whether the axis of revolution is OX, or OY.

The value of ds is worked out by differential equations on p. 45 and the limits of the integral are determined by the coordinates of the extremities of the meridian section.

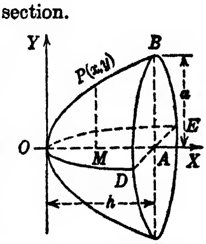

FIG. 79. Paraboloid.

Examples. (1) Find the length of arc of one arch of a cycloid (Art. 19) with the equations $x = a(\theta - \sin\theta)$, $y = a(1 - \cos\theta)$.

Differentiating, $dx = a(1 - \cos\theta)d\theta$, $dy = a \sin\theta\, d\theta$.

Hence $dx^2 + dy^2 = a^2[(1 - \cos\theta)^2 + \sin^2\theta]\, d\theta^2 = 2a^2(1 - \cos\theta)d\theta = 4a^2 \sin^2 (1/2\, \theta)\, d\theta$ (Art. 15).

Then $s = \int \sqrt{dx^2 + dy^2} = \int 2a \sin 1/2\, \theta\, d\theta$. Limits are 0° and 360°.

$$s = -4a \cos 1/2\, \theta \Big]_0^{360°} = 4a + 4a = 8a.$$

(2) Find the volume and surface of the paraboloid, Fig. 79, if $OA = h$, $AB = AD = a$.

The equation of the meridian section OPB is $y^2 = a^2x/h$. Then $V = \pi \int y^2 dx = \pi \int a^2x/h \cdot dx = \pi a^2x^2/2h$, with limits $x = h$, $x = 0$. Hence $V = \pi a^2h/2$, that is, the area of the base $BDCE$ times half of the height OA.

To find the area of the surface, calculate $ds = \sqrt{1 + (dy/dx)^2}\,dx$. Differentiating $y^2 = a^2x/h$, the result is $2y\,dy/dx = a^2/h$, from which $dy/dx = a^2/2hy$. Hence $ds = \sqrt{1 + a^4/4h^2y^2}\,dx = \sqrt{4h^2y^2 + a^4}\,dx/2hy$.

Then $S = 2\pi\int y\,ds = \pi/h\int\sqrt{4h^2y^2 + a^4}\,dx = a\pi/h\int\sqrt{4hx + a^2}\,dx = a\pi(4hx + a^2)^{3/2}/6h^2$ (using formula (43), Table 12, $n = 1$). Limits are $x = h$, $x = 0$.

Hence $S = \pi a\,[(4h^2 + a^2)3/2 - a^3]/6h^2$.

Length of arc. End-points (x_1, y_1), (x_2, y_2), in rectangular co-ordinates; or (ρ_1, θ_1), (ρ_2, θ_2), in polar co-ordinates; s = length

$$s = \int\sqrt{dx^2 + dy^2} = \int_{x_1}^{x_2}\sqrt{1 + (dy/dx)^2}\,dx = \int_{y_1}^{y_2}\sqrt{(dx/dy)^2 + 1}\,dy.$$

$$s = \int\sqrt{d\rho^2 + \rho^2 d\theta^2} = \int_{\theta_1}^{\theta_2}\sqrt{(d\rho/d\theta)^2 + \rho^2}\,d\theta = \int_{\rho_1}^{\rho_2}\sqrt{1 + (\rho d\theta/d\rho)^2}\,d\rho.$$

The derivative dy/dx, or $d\rho/d\theta$, must be found from the equation (rectangular or polar) of the curve, and the radical reduced to a function of the variable involved in the differential.

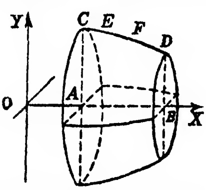

FIG. 80. Solid of revolution.

Volume of a solid of revolution. Axis of revolution OX (Fig. 80); meridian section $y = f(x)$, $x = a$, $x = b$, at extremities of meridian section. $OA = a$, $OB = b$, equation of $CEFD$ is $y = f(x)$, V = volume

$$V = \pi\int_a^b y^2 dx$$

Axis of revolution OY, meridian section $x = h(y)$, $y = c$, $y = d$, at extremities of meridian section.

$$V = \pi\int_c^d x^2 dy.$$

Integration as a summation. A definite integral is the limit of a sum of differential (infinitesimal) elements. Many useful applications of integral calculus depend upon the fundamental theorem: Given a function $f(x)$ continuous in interval from $x = a$ to $x = b$. Let this interval (Fig. 81) be divided into any number (n) of parts of respective lengths Δx_1, $\Delta x_2 \ldots$, Δx_n. On each of these segments take a point, and let the values of x at these points be $x_1, x_2, \ldots, x_n$, respectively. Then the corresponding values of $f(x)$ are $f(x_1)$, $f(x_2), \ldots, f(x_n)$. Form the sum of the products of each of these values of $f(x)$ by the length of the corresponding segment, namely the sum, $f(x_1)\Delta x_1 + f(x_2)\Delta x_2 + \ldots + f(x_n)\Delta x_n$. Let the number of segments be increased indefinitely so that the length of each approaches zero, then the limiting value of the above sum is the value of the integral of $f(x)dx$ evaluated for limits $x = a$, $x = b$. In the usual notation,

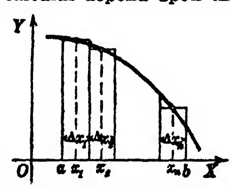

FIG. 81. Graphical integration.

$$\int_a^b f(x)dx = \underset{n=\infty}{\text{Limit}}\,(f(x_1)\Delta x_1 + f(x_2)\Delta x_2 + \ldots + f(x_n)\Delta x_n).$$

Each term of the sum in the right-hand member is a DIFFERENTIAL ELEMENT. The value of the theorem lies in affording means of calculating the limit of a sum of differential elements of a certain form. The theorem has wide application.

In Fig. 81, the curve is $y = f(x)$; the products $f(x_1)\Delta x_1$, etc., are the areas of rectangles; the sum of the products is approximately the area under the curve, and the limit of the sum is the exact area. But this also equals the definite integral in the left-hand member in the above equation.

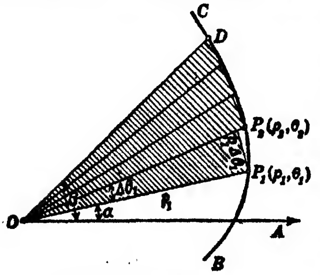

FIG. 82. Area of a sector.

Examples. (1) Area swept over by radius vector in Fig. 82 is the limit of the sum of the circular sectors with radii ρ_1, ρ_2, etc., and central angles $\Delta\theta_1$, $\Delta\theta_2$, etc., hence of area $1/2\ \rho_1^2\Delta\theta_1$, $1/2\ \rho_2^2\Delta\theta_2$, etc. (see Art. 13). The fundamental theorem leads at once to the formula (p. 53) $A = 1/2\int\rho^2 d\theta$.

(2) Volume of solid of revolution about OX (Fig. 83) may be considered the limit of the sum of circular cylinders with altitudes Δx_1, Δx_2, etc., and base radii y_1, y_2, etc., hence of volumes $\pi y_1^2\Delta x_1$, $\pi y_2^2\Delta x_2$, etc. The fundamental theorem gives immediately $V = \pi\int y^2 dx$ (see p. 53).

(3) Volume of irregular solid. A certain solid answers the following description: the base is an ellipse with semi-axes a, b; plane sections standing on the base and perpendicular to the major axis are squares. Find the volume.

With axes OX, OY in the base (Fig. 84), the equation of the ellipse is $b^2x^2 + a^2y^2 = a^2b^2$, or $y^2 = b^2(a^2 - x^2)/a^2$. Divide the solid into slices of equal infinitesimal thickness Δx by sections perpendicular to OX, and consider these slices trimmed into rectangular blocks such as $PQMN - P'Q'M'N'$.

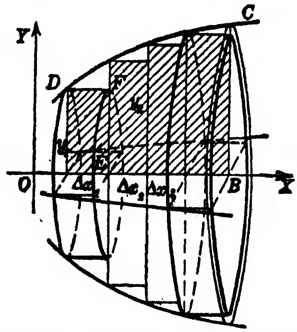

FIG. 83. Volume of solid of revolution.

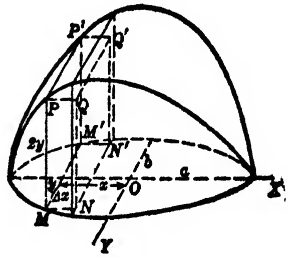

FIG. 84. Ex. 3, p. 55.

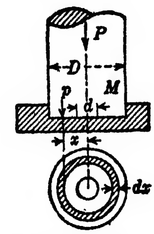

FIG. 85. Thrust bearing.

The co-ordinates of M are (x, y). The volume of this block $= 4y^2\Delta x$. Then the required volume is the limit of the sum of all such blocks when the thickness (Δx) approaches zero. Hence

$$V = \int 4y^2 dx = 4\int b^2(a^2 - x^2)/a^2 \cdot dx = 4b^2(a^2x - 1/3x^3)/a^2$$

substituting the value of y^2 from equation of base. The limits are $x = -a$, $x = a$, giving $V = 16ab^2/3$.

(4) Work expended in friction in thrust bearings. A vertical shaft M turns in a bearing (Fig. 85). At a distance x in. from the axis of the shaft let the normal pressure on the bearing due to load P lb. in the direction of the shaft axis be p lb. per sq. in. (unit normal pressure). Then the normal pressure on an infinitesimal ring of radius x and width dx is $p \times 2\pi x\, dx$ (since $2\pi x\, dx$ = the area of the ring). Then the load P must equal the sum of the normal pressures on all such infinitesimal rings, that is, $P = 2\pi \int px\, dx$. Let f = the coefficient of sliding friction. Then the work expended in one revolution in friction on an infinitesimal ring $= fp \times 2\pi x\, dx$ times the circumference of the ring ($2\pi x$). Hence the total work expended, W, is the sum of the above elements of work for all such rings, that is, $W = 4\pi^2 f \int px^2dx$ in in.-lb. The relation between W and P is $W = 2\pi fP \int px^2dx \div \int px\, dx$. For a collar bearing the limits are $x = 1/2\, d$, $x = 1/2\, D$. If p is everywhere constant (the usual assumption),

$$W = fP \times 4\pi(D^3 - d^3)/3(D^2 - d^2).$$

(5) Center of gravity. Plane line. Divide the line into infinitesimal parts of length ds, multiply each ds by its perpendicular distance r from a given axis in the plane of the line, add all such products, which gives the STATIC MOMENT M of the line with respect to the axis, or $M = \int r\, ds$. Divide M by the length of the line and the result is the perpendicular distance of the center of gravity C from the given axis. A similar argument holds for plane areas, solids of revolution, etc. The formulas follow. Center of gravity is C.

Plane line. Let $C = (x_0, y_0)$; (x, y) any point on the line; L = length of line; $x_0 = \int x\, ds/L_1$; $y_0 = \int y\, ds/L_1$.

Plane area, bounded by a curve and the rectangular axes OX, OY (Fig. 86). $C = (x_0, y_0)$. A = area. (x, y) = any point on the boundary curve. $x_0 = \int xy\, dx/A$; $y_0 = \int xy\, dy/A$.

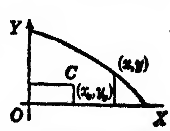

FIG. 86. C.g. plane area.

Solid of revolution. Let OX be the axis of revolution, V = volume, x_0 = distance of C from origin. The equation of the meridian section is $y = f(x)$. $x_0 = \pi \int xy^2dx/V$.

(6) Moment of inertia. The argument is the same as in Ex. 5 above, except that each infinitesimal length is multiplied by r^2. Hence the moment of inertia $I = \int r^2ds$. In the following formulas, the subscript indicates the AXIS OF REFERENCE.

Plane line $I_x = \int y^2ds$; $I_y = \int x^2ds$; (x, y) = any point on line.

Plane areas as in Fig. 86. $I_x = \int y^2x\, dy$; $I_y = \int x^2y\, dx$; (x, y) = any point on boundary curve.

Approximate integration. Evaluation of $\int_a^b f(x)dx$. When a definite integral cannot be worked out by the tables available, an approximate value may be found by one of the following rules:

(1) Expand $f(x)$ into a power series (Art. 22), integrate term by term, and evaluate the new series for the given limits.

(2) Plot the curve $y = f(x)$. The numerical measure of the area between the curve, the X-axis, and the ordinates at $x = a$ and $x = b$ is the value of the integral.

(*a*) Find this area by counting squares of cross-section paper.

(*b*) Use Simpson's Rule, Art. 13.

(*c*) Use a planimeter or integraph (MECHANICAL QUADRATURE). (16)

25. DERIVATION OF FORMULAS FOR EXPERIMENTAL DATA

To determine a formula (EMPIRICAL EQUATION) satisfied by given experimental data, when the law obtaining in the experiment is unknown, the data should be plotted on cross-section paper and the equation of a curve to "fit the points" derived. The curve need not pass through all plotted points; derivation of an equation satisfied exactly by the given data is not the object, since such data are subject to errors of determination; a simple formula fulfilling the conditions with a degree of accuracy warranted by the data is the end desired.

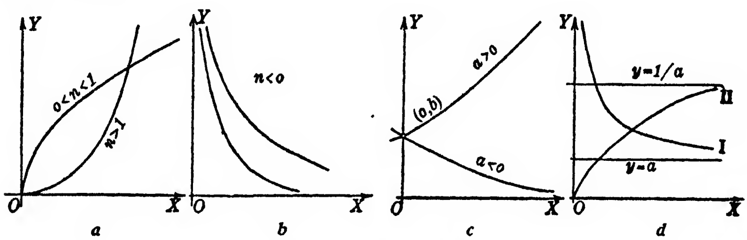

FIG. 87. Type laws.

Acquaintance with several standard curves (Fig. 87) will assist in choosing the formula to be tested. Comparison of the curve suggested by the graph of the given data with these figures will suggest the law to be tried.

Two-constant laws are:

(1) STRAIGHT-LINE LAW: $y = mx + b$.

(2) POWER LAW: $y = ax^n$. (Fig. 87, items *a*, *b*.)

(3) EXPONENTIAL LAW: $y = be^{ax}$. (Fig. 87, item *c*.)

(4) HYPERBOLIC LAWS: $y = (ax + b)/x$. (Fig. 87, item *d*, curve I.)
$y = x/(ax + b)$. (Fig. 87, item *d*, curve II.)

Straight-line law. Test for a straight-line law may be made with a straight-edge; the test is affirmative when deviations from the straight line are small, some positive and some negative, and curve has no systematic curvature.

Constants in a straight-line formula may be determined by:

1. Selected points. Two points on the plot may be selected such that a straight line drawn through them gives satisfactory distribution of all points. If the corresponding values selected are (x_1, y_1) and (x_2, y_2), solve the simultaneous equations $y_1 = mx_1 + b$ and $y_2 = mx_2 + b$, for the constants m and b, and place these values in the formula $y = mx + b$.

2. Method of averages. Substitute each pair of given values of x and y in the formula $y = mx + b$, thus forming the OBSERVATION EQUATIONS (equal in number to the number of determinations of x, y in the experiment); divide these observation equations into two groups as nearly equal in number as possible; add together all equations of each group to obtain one final equation for each group, and solve these final equations for m and b. Place the resulting values of m and b in the formula $y = mx + b$.

Example. In an experiment with a pulley, the effort E lb. required to raise a load W lb. was found to be as in Table 13.

Solution. (1) A straight line drawn through (30, 6 1/4) and (100, 16 1/2) on rectangular co-ordinates fits the points well. Substituting these values in $y = mx + b$, equations are $6.25 = 30m + b$, $16.5 = 100m + b$. Solving, $m = 0.146$, $b = 1.86$. Hence the law is $E = 0.146W + 1.86$.

(2) Take first 5 observation equations, $3\ 1/4 = 10m + b, \ldots, 9 = 50m + b$, and add them; result is $30\ 7/8 = 150m + 5b$. Taking last 5, namely $10\ 1/2 = 60m + b, \ldots 16\ 1/2 = 100m + b$, and adding, $68 = 400m + 5b$. Solving, $m = 0.148$, $b = 1.72$. Hence result, $E = 0.148W + 1.72$.

Table 13. Data from pulley experiment

W	E	W	E
10	3 1/4	60	10 1/2
20	4 7/8	70	12 1/4
30	6 1/4	80	13 3/4
40	7 1/2	90	15
50	9	100	16 1/2
(150)	(30 7/8)	(400)	(68)
(Totals)			

3. Method of least squares. If the degree of accuracy of the experiment warrants, which is not often the case with engineering data, the method explained in Art. 11 may be used.

Power law. Test for power law $y = ax^n$. If the graph suggests a curve of the type in Fig. 87, item *a* or *b*, the test to apply is to plot the points ($\log x$, $\log y$). If a power law holds, a straight line will fit these points, because from $y = ax^n$, it follows that $\log y = \log a + n \log x$; or, putting $\log y = y'$, $\log a = a'$ and $\log x = x'$, the result is $y' = a' + nx'$ which is the equation of a straight line. The constants n and a' are found as described above; and a comes from $\log a = a'$. Values of a and n placed in $y = ax^n$ will give the desired equation.

Logarithmic cross-section paper, constructed by laying off logarithmic scales (Art. 1) on each of two perpendicular axes with the intersection marked 1 on both, drawing lines through the points of division parallel to the axes, and marking them with their numerical (not logarithmic) values, makes it possible to plot logarithms of data directly, and thus test for a power law without looking up logarithms.

Example. Pressure (p = pounds per square inch) and volume (v = cubic feet) of 1 lb. of saturated steam were measured as in Table 14. Find a law for the data.

Table 14. P-V data

v	p
4	110
4.5	97.1
5	86.8
5.5	78.4
6	71.5
7	60.7

Table 14a

v'	p'	v'	p'
0.6021	2.0414	0.7404	1.8943
0.6532	1.9872	0.7782	1.8543
0.6990	1.9385	0.8451	1.7832
(1.9543)	(5.9671)	(2.3637)	(5.5318)

Solution. The curve suggested on a rectangular plot is of the type in Fig. 87, item *b*. A test on logarithmic cross-section paper shows that a power law, $p = av^n$, applies. To find the equation, tabulate values of $\log v = v'$ and $\log p = p'$ (Table 14*a*), the relation being $p' = a' + nv'$ ($\log a = a'$), and apply the method of averages (see Table 13).

The averages, substituted in the equations, are, $5.9671 = 3a' + 1.9543n$ and $5.5318 = 3a' + 2.3637n$. Solving, $n = -1.063$, $a' = 0.6925$. $a = 480$. $p = 480v^{-1.063}$, or $pv^{1.063} = 480$.

Exponential law. Test for exponential law $y = be^{ax}$. Plot the experimental points as (x, $\log y$). If a straight line fits these points, an exponential law holds.

To verify this statement, take logarithms of both members of the equation, which gives $\log y = \log b + ax \log e$. Putting $\log y = y'$, $\log b = b'$, $a \log e = a'$, the result is $y' = b' + a'x$, which is the equation of a straight line.

Semi-logarithmic cross-section paper is constructed by laying off a logarithmic scale (Art. 1) from the origin on one axis of co-ordinates, and drawing lines through points of division parallel to the other axis. Draw equidistant lines parallel to the first axis. Points (x, $\log y$) can be plotted quickly on such paper without determination of the actual logarithms, and testing the data for an exponential law is thus expedited.

Hyperbolic laws. Equation $y = (ax + b)/x$ may be written $xy = ax + b$. Hence points (x, xy) lie on a straight line. Equation $y = x/(ax + b)$ is the same as $x/y = ax + b$, and therefore the points (x, x/y) lie on a straight line.

Three-constant laws are:

(5) $y = a + bx + cx^2$ (PARABOLIC LAW), (7) $y = ax^n + c$,

(6) $\log y = a + bx + cx^2$, (8) $y = be^{ax} + c$.

When given values of x differ by a constant increment Δx (Art. 20), points (x, Δy) will follow a straight-line law if Eq. 5 applies, and points (x, $\Delta \log y$), if Eq. 6 holds. Curves

for Eqs. 7 and 8 differ from Fig. 87, items *a*, *b*, and *c*, respectively, only in the position of the X-axis. (Line $y - c = 0$ has the same relation to the curves as the X-axis in the figures named.) Value of c can often be found by trial and y replaced by $y - c$ in the methods explained above. (**16, 17, 18.**)

26. CHARTS FOR EMPIRICAL FORMULAS

The following material deals with methods of so treating formulas involving several variables that corresponding values of these variables can be read immediately from a chart. The methods possess wide application.

Notation. The variables are denoted by z, z_1, z_2, z_3, etc., and functions $f(z)$, $f(z_1)$, $F(z_1)$, $g(z_2)$, etc., of them by f, f_1, F_1, g_2, etc.

Function scales. The logarithmic scale (Art. 1) is a simple example of a function scale. In general, to construct a function scale for $f(z)$, lay off on a line a uniform scale of lengths with decimal subdivisions, calculate $f(z)$ for a number of values of z occurring in the given problem, lay off these values on the scale of lengths, and inscribe at each point thus located the corresponding value of z. If values of $f(z)$ are denoted by x, then $x = f(z)$ is called the equation of the function scale. In practice a SCALE FACTOR m (a constant) is introduced, *i.e.*, the equation of the scale is written $x = m f(z)$. The value of the scale factor in any given case is found as follows:

Example. Required a scale 10 in. long for log z when z varies from 0.01 to 100. *Solution.* Values of log z run from -2 to 2, a range of 4 units. Since $10/4 = 2.5$, the equation of the scale is $x = 2.5 \log z$. Generally, if the length of the scale is L in. and the range of values of the function is Z units, $m = L/Z$.

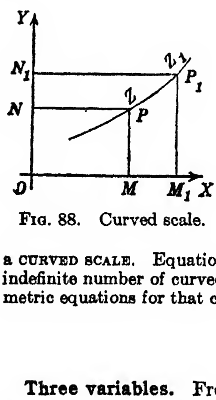

FIG. 88. Curved scale.

Only a limited number of values of z appear on the scale; division marks indicate intermediate values. The subdivisions of the uniform scale of lengths may be retained when readings of values of $f(z)$ are desired. The function scales for $m\,f(z)$ and $m\,f(z) + c$ (c = a constant) are identical; the addition of a constant simply shifts the scale constructed for $m\,f(z)$ along the scale of lengths. If values of $f(z)$ are large, either a scale for $m\,f(z)$, where m is small, may be constructed or a scale for $f(z) - c$, where c is large. The function scales thus far discussed, being laid off on a straight line, are called STRAIGHT SCALES.

Curved scales. Let the straight scales $x = f(z)$ and $y = g(z)$ be constructed on perpendicular axes. Let M and N (Fig. 88) be points with the same value of z. Plot $x = OM$, $y = ON$. Again, let z have the same value z_1 at M_1, N_1. Plot P_1. Draw a smooth curve through all such points, and mark at each point corresponding values of z. The result is a CURVED SCALE. Equations $x = f(z)$, $y = g(z)$ are parametric equations of the curve. (Art. 18.) An indefinite number of curved scales may be constructed on any curve, corresponding to different parametric equations for that curve.

Charts with a Network of Lines

Three variables. From the explanation below it will appear that the object is to construct three systems of curves such that corresponding values of the variables are attached to three curves through a common point. In the examples given, such a system of curves is composed of straight lines and is easily constructed. In other cases the labor involved is so great that another type of chart is preferred. (See *Alignment Charts.*)

Type 1. $f_2 = f_1 + f_3$. On perpendicular axes OX, OY (Fig. 89) construct the scales $x = m_1 f_1$, $y = m_2 f_2$, and draw a network of parallels to the axes through the points of division. Construct the system of parallel lines $y = m_2 x/m_1 + m_2 f_3$ which result by assigning to z_3 the values used in the problem, and mark on each line the corresponding value of z_3, called the PARAMETER of the system. The values of z_1, z_2, z_3 attached to any three lines in the diagram through a point will satisfy the equation. From the given data it may be desirable to use the scales $x = m_1 f_1 + c_1$, $y = m_2 f_2 + c_2$. Parallel lines are now $y = m_2(x - c_1)/m_1 + m_2 f_3 + c_2$. In practice such constants are usually introduced. See Ex. 1 below.

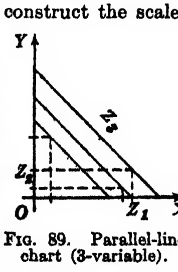

FIG. 89. Parallel-line chart (3-variable).

Type 2. $f_2 = f_1 f_3$. Construct scales $x = m_1 f_1$, $y = m_2 f_2$ as in Type 1, and the system of lines $y = m_2 f_3 x/m_1$ intersecting at $O(x = 0, y = 0)$. (Fig. 90.) If MP and NP are drawn through the extremities of the scales on OX and OY, the values of z_3 may be conveniently written along these lines.

If the scales $x = m_1 f_1 + c_1$, $y = m_2 f_2 + c_2$ are used, the system of lines is $y - c_2 = m_2 f_3 (x - c_1)/m_1$, passing through (c_1, c_2). Transforming $f_2 = f_1 f_3$ by taking logarithms gives $\log f_2 = \log f_1 + \log f_3$, which is in the form of Type 1.

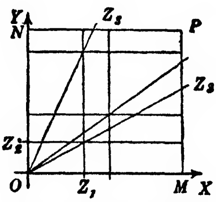

FIG. 90. Radiating-line chart (3-variable).

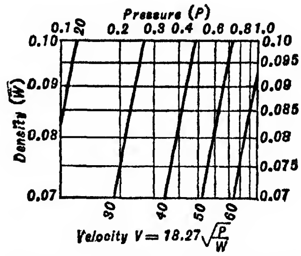

FIG. 91. Pitot-tube chart (parallel).

Example 1. Fig. 91 is a chart for $V = 18.27\sqrt{P/W}$, the formula for measurement of velocity of air by a Pitot tube. Taking logarithms and transposing, $\log W = \log P - 2 \log (V/18.27)$, which is Type 1. The scales used are $y = 25 \log 10W$, $x = 5 \log 10P$. The system of parallel lines is $y = 5x - 50 \log (V/18.27)$. Values of V are marked on the ends of the lines. This example illustrates logarithmic transformation of a given formula to bring it under Type 1.

Example 2. The preceding equation may be written $P = 0.003\,Wv^2$, and then comes under Type 2. Fig. 92 shows a chart, with scales $y = 5P$, $x = 100W$, and lines $y/x = 0.00015\,v^2$. Equations of the bounding vertical lines are $x = 6$, $x = 10$; of the bounding horizontal lines, $y = 0.5$, $y = 5$. Uniform scales are laid off on these lines. The system of lines for v may be plotted by calculating the points of intersection with the bounding lines, or also, by drawing lines through $x = 0$, $y = 0$, which is in this case a point off the chart.

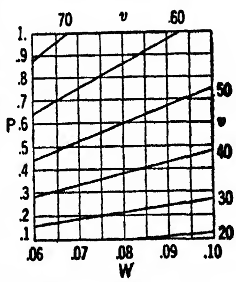

FIG. 92. Pitot-tube chart (radiating).

Four variables. Extensions of the preceding methods are shown in Fig. 93.

Type 3. $f_1 + f_2 = f_3 + f_4$. (Fig. 93, item *a*.) Construct the function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + c_3$ on PQ, and two systems of parallel lines, (1) $y = m(x - c_1)/m_1 + m f_2$, with parameter $z_2 (AB$, etc.); (2) $y = m(x' - c_3)/m_3 + m f_4$, with parameter $z_4 (CD$, etc.). Corresponding values of z_1, z_2, z_3, z_4 are determined as indicated in the figure.

Type 4. $f_1 f_2 = f_3 + f_4$. (Fig. 93, item *b*.) Construct function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + c_3$ on PQ, and two systems of lines, (1) $y = m f_2 (x - c_1)/m_1$, with parameter z_2 (lines through $O(c_1, 0)$, OA, etc.), (2) $y = m(x' - c_3)/m_3 + m f_4$, with parameter z_4 (parallel lines CD, etc.). Corresponding values of z_1, z_2, z_3, z_4 are indicated in the figure.

Type 5. $f_1 f_2 = f_3 f_4$. (Fig. 93, item *c*.) Construct function scales $x = m_1 f_1 + c_1$ on OM, $x' = m_3 f_3 + a$ on PQ, $(OM = a)$, and two systems of lines; (1) $y = m f_2 (x - c_1)/m_1$,

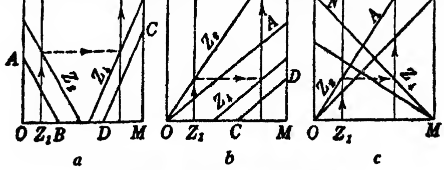

FIG. 93. Four-variable charts.

with parameter z_2 (lines through $O(c_1, 0)$), and (2) $y = m f_4 (x' - a)/m_3$, with parameter z_4 (lines through M). Corresponding values of z_1, z_2, z_3, z_4 appear in the figure.

Example 1. Fig. 94 shows a portion of a chart for $N_s = \text{R.P.M.}\ \sqrt{\text{H.P.}}/h^{5/4}$, which is the formula for the specific speed (N_s) for impulse and reaction water wheels. Taking logarithms, $\log N_s - 1/2 \log$

H.P. = log R.P.M. − 5/4 log h. This comes under Type 3. The scales are $y = 3.3 \log 0.001$ H.P., $y' = -3.3 \log 0.01\ h$, both of which are laid off on the line $x = 3 \log 3$. The systems of parallel lines are $4.4x - 5y' = 13.2 \log 0.3$ R.P.M., $2.2x + y = 6.6 \log 3N_s$. The Y-axis is off the chart. For lines

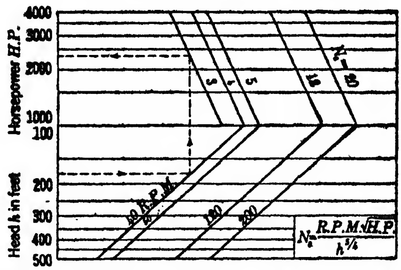

FIG. 94. Specific speeds for impulse water wheels.

of the two systems intersecting on the X-axis (horizontal line in figure through $h = 100$), R.P.M. = $10N_s$.

Example 2. Fig. 95 shows the lower part of a chart for T.E. = $0.85d^2\ PS/D$, which is the formula for the tractive effort of a simple two-cylinder locomotive, with boiler pressure $P = 200$ lb./in.^{2} The formula may be written $170\ d^2\ S$ = T.E. × D, and comes under Type 5. The scales are $x = 0.0085\ d^2$, $x' = 12 - 0.75\ T/10{,}000$, both laid off on horizontal lines. The two systems of lines are (1) $y = Sx/30$, (2) $y = D(12 - x')/45$.

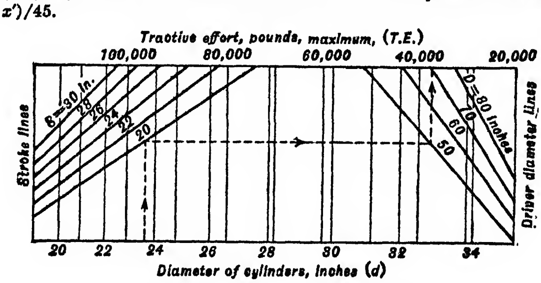

FIG. 95. Tractive effort of a locomotive.

Alignment charts. For many formulas in engineering it is possible to construct function scales in such a way that readings on them at points on one or more lines will satisfy the formula. Many of these charts are simple and easily constructed. Alignment charts for Types 1 to 5 above are given below.

Type 6. $f_1 + f_2 = f$. (Fig. 96, item *a*.) Scales for m_1f_1, m_2f_2, mf are constructed on parallel axes with the conditions $m_1/m_2 = a/b$, $m = m_1m_2/(m_1 + m_2)$, and adjusted so

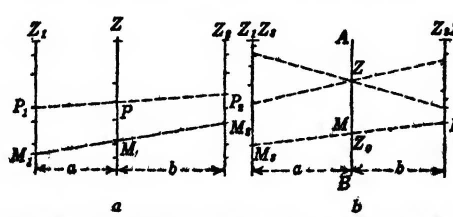

FIG. 96. Construction of alignment charts, Types 6, 7.

that readings at M_1, M, M_2 will satisfy the equation. Then readings at any three points P_1, P, P_2, in line, will also satisfy the formula.

Type 7. $f_1 + f_2 = f_3 + f_4$. (Fig. 96, item *b*.) Scales for m_1f_1, m_2f_2 are constructed on one axis and scales for m_3f_3, m_4f_4 on a parallel axis, with $m_1 = m_3$, $m_2 = m_4$. A third axis AB is then drawn so that $m_1/m_2 = a/b$. Set $f_1 + f_2 = z$ and $f_3 + f_4 = z$. Chart the first of these equations as in Type 6, and compute $z(= z_0)$ at some point as M. No scale for z on AB need be constructed. Chart the second equation, adjusting the scales for

m_3f_3, m_4f_4 so that readings at M_3, $M(z_0)$, M_4 on a line $M_3M\,M_4$ will correspond. If any two lines intersect on AB, readings for z_1, z_2, on one line, and z_3, z_4, on the other line, will satisfy the equation.

Example. Fig. 97 is a chart for $N_c = 1{,}550{,}000\, d^2/W^{1/2}l^{3/2}$, which is a formula for the determination of the critical speed of a shaft when the load is concentrated midway between the bearings. Taking logarithms, $\log N_c + 1/2 \log W - \log 1{,}550{,}000 = 2 \log d - 3/2 \log l$, which is the form of Type 7. Scales are laid off for $10 \log d$, and $3.75 \log l$ with $m_3/m_4 = -2$, hence with axis AB to the right. The line through $d = 1$, $l = 1$ cuts AB in $z = 0$. For N_c, the scale is $5 \log N_c$. The line joining $N_c = 15{,}500$ and $z = 0$ must cut the W-scale at $W = 10{,}000$. The scale for W is $-1.25 \log W$.

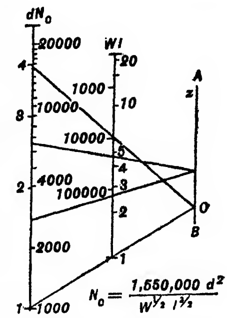

FIG. 97. Critical speed of a shaft with center-concentrated load.

Type 8. $f = f_1/f_2$. (Fig. 98, item *a*.) Construct scales for m_1f_1, $-m_2f_2$ on parallel axes, and adjust these so that line AB drawn from $A(f_1 = 0)$ to $B(f_2 = 0)$ makes a convenient angle with AM (usually 45°). On AM construct a scale for $x = am_1f/(m_2 + m_1f)$. Project these graduations on to AB by lines parallel to the axes, and mark at these points on AB the same values for z as on AM. Values of z_1, z, z_2 on any transversal will satisfy the equation. This type is called a Z-chart.

Type 9. $f_1/f_2 = f_3/f_4$. (Fig. 98, item *b*.) Construct scales for m_1f_1, $-m_2f_2$, m_3f_3, $-m_4f_4$, with $m_1/m_2 = m_3/m_4$, on axes as indicated, with $f_1 = f_3 = 0$ at A, $f_2 = f_4 = 0$ at B. Transversals intersecting on diagonal AB will cut the scales in corresponding values of z_1, z_2, z_3, z_4.

Type 10. $f_1 + f_2 = f_3/f_4$. (Fig. 98, item *c*.) Lay off scales for m_1f_1, m_3f_3 on AM starting at A ($f_1 = f_3 = 0$), scale for m_4f_4 on AB from A ($f_4 = 0$), scale downward for m_2f_2 from B ($f_2 = 0$) on BQ, with $m_1 = m_2$, and $m_3/m_4 = m_1/AB$. Parallel index lines will cut the scales in corresponding values of the variables, z_3, z_4, on one line, and z_1, z_2, on the other.

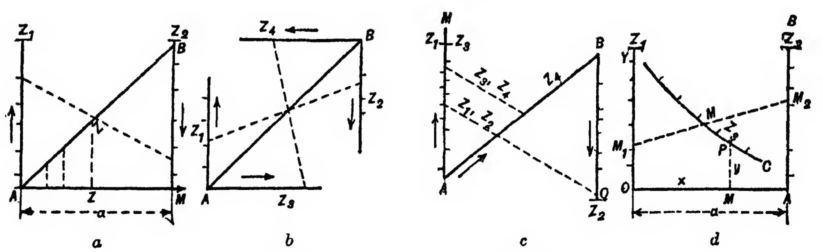

FIG. 98. Construction of alignment charts, Types 8 to 11.

Type 11. $f_1 + f_2f_3 = F_3$. (Fig. 98, item *d*.) This type brings in a curved scale. (Fig. 88.) Construct the scales $y_1 = OM_1 = m_1f_1 + c_1$, $y_2 = AM_2 = m_2f_2 + c_2$, and the curved scale $x = OM = am_1f_3/(m_2 + m_1f_3)$, $y = MP = (m_1m_2F_3 + m_2c_1 + m_1c_2f_3)/(m_2 + m_1f_3)$, on the curve C. Readings on any transversal $M_1M\,M_2$ will satisfy the equation.

For other types, some of which are extensions of the preceding, see (**16, 17, 18, 19**).

BIBLIOGRAPHY

(1) A good presentation of computation, errors, etc., is given by Langley, *A treatise on computation* (Longmans). (2) A short list follows. Wentworth and Smith, *Trigonometric and logarithmic tables, five places* (Ginn & Co.); *Wiley trigonometric tables, five places* (Wiley & Sons); Marsh, *Interpolated six-place tables of the logarithms of numbers* (Wiley & Sons); Hutton, *Mathematical tables, seven places* (London); Ives, *Seven-place natural trigonometrical functions* (Wiley & Sons). (3) A good explanation of the slide rule with numerous problems is given by Keal, Phelps, and Leonard, *The slide rule* (Wiley & Sons). See also pamphlets published by manufacturers, for example, Cox, *The Mannheim slide rule* (Keuffel & Esser Co.). Many other types of slide rules are on the market, some of which are designed for the solution of special problems. For illustrations and descriptions of these as well as a great variety of calculating machines see *Methods of calculation, a handbook of the Exhibition at the Napier Tercentenary Celebration* (G. Bell & Sons, London). (4) For an excellent text-

book on elementary algebra see Hawkes, Luby, and Touton, *Complete school algebra* (Ginn & Co.); (5) Hawkes, *Advanced algebra* (Ginn & Co.); Hall and Knight, *Higher algebra* (Macmillan Co.); Wentworth, *College algebra* (Ginn & Co.). a Corrections to be *added* for a fourth figure 1, 2, 3, 4, 5 are given in right-hand columns. For a fourth figure 6, 7, 8, 9, take the tabular entry for the next larger number of three figures and *subtract* the correction given for 4, 3, 2, 1, respectively.

If decimal point is moved *one* place in *N*, move it *two* places in the tabular number.

N	0	1	2	3	4	5	6	7	8	9	1	2	3	4	5

a **CAUTION.** Tabular values *decrease* with *increasing* N, hence corrections for a fourth figure 1, 2, 3, 4, 5 must be *subtracted* from the tabular value given for the first three figures of N. For a fourth figure 6, 7, 8, 9, *add* to the tabular value given for the next larger number the correction for 4, 3, 2, 1, respectively. If decimal place in N is moved to *right* (or *left*), move it the same number of places to *left* (or *right*) in tabular value.

Table 9. Reciprocals of numbers—*Continued*

a Move decimal point one place in *circumference,* two places in *area,* if decimal point is moved one place in D. If circumference C or area A is given, diameter D is found by $D = 0.31831C = 1.12838\sqrt{A}$.

Table 10. Circles, circumferences and areas (diameters in hundredths)—*Continued*

									Prop. parts				

Logarithmic cosines. Read up. Subtract proportional parts.

a Annex −10 to tabular values. Interpolation will be inaccurate for logarithmic sines and tangents of angles less than 6°, and for cosines and cotangents of angles greater than 83°. Five- or more-place tables should be consulted for such angles.

Table 24. Logarithmic sines—*Continued*

a Sinh $u = {}^1/_2(e^u - e^{-u})$, cosh $u = {}^1/_2(e^u + e^{-u})$, tanh u = sinh u/cosh u. Other hyperbolic functions are sech u = 1/cosh u, cosech u = 1/sinh u, coth u = 1/tanh u. Other relations are $\cosh^2 u - \sinh^2 u = 1$, $\operatorname{sech}^2 u = 1 - \tanh^2 u$. Avoid interpolation for $u > 1$.

Trigonometric and hyperbolic functions satisfy the equations $\sin ui = i \sinh u$, $\cos ui = \cosh u$, ($i = \sqrt{-1}$), see Sec. 21, Art. 10.

* The American petroleum industry has adopted the tierce, 42 gal., as its barrel.
† British Imperial gallon = 1.20091 U. S. gal.

Capacity metric. The liter (l.) is the unit and the equivalent of the volume occupied by the mass of 1 kilogram of pure water at maximum density. The smaller units usually employed are the cubic centimeter (cu. cm. or cc.) and the cubic millimeter (cu. mm. or $mm.^3$) which are, for all practical purposes, 0.001 and 0.000001 liter respectively.

Table 42. Equivalent forces or weights per unit of volume

1 dyne per cu. cm. = 0.00101979 $gm./cm.^3$ = 0.00118528 $poundal/in.^3$

Table 46. Composition and specific gravity of minerals

Mineral	Composition	Sp. gr.[a]
Acanthite	Ag_2S	7.2
Actinolite	$Ca(Mg\cdot Fe)_3(SiO_3)_4$	3.1
Agate	Quartz	...
Alabandite	MnS	4.0
Alaskaite	$PbS\cdot Bi_2S_3$	7.0
Albertite	Asphaltum	1.1
Albite	$NaAlSiO_3$	2.6
Almandite	$Fe_3Al_2(SiO_4)_3$	4.0
Altaite	$PbTe$	8.2
Alunite	$K_2O\cdot 3Al_2O_3\cdot 4SO_3\cdot 6H_2O$	2.65
Alunogen	$Al_2(SO_4)_3 + 18H_2O$	1.7
Amalgam	Ag_xHg_y	14
Amblygonite	$Li(AlF)PO_4$	3.05
Amosite	$(Fe, Ca, H_2, Mn)O\cdot SiO_2$	2.25
Analcite	$NaAlSi_2O_6 + H_2O$	2.25
Andalusite	Al_2SiO_5	3.2
Andradite	$Ca_3Fe_2(SiO_4)_3$	3.85
Anglesite	$PbSO_4$	6.25
Anhydrite	$CaSO_4$	2.9
Ankerite	$CaCO_3\cdot(Mg, Fe, Mn)CO_3$	3.0
Annabergite	$Ni_3As_2O_8 + 8H_2O$	...
Anorthite	$CaAl_2Si_2O_8$	2.75
Anthophyllite	$(Mg\cdot Fe)SiO_3$	3.1
Anthracite	Hydrocarbon	1.3–1.8
Antimony	$Sb(\pm As, Fe, Ag)$	6.6
Apatite	$(Cl\cdot F)Ca_5(PO_4)_3$	3.2
Apophyllite	$H_7KCa_4(SiO_3)_8 + 4\,{}^1/_2H_2O$	2.35
Aragonite	$CaCO_3$	2.94
Argentite	Ag_2S	7.3
Arsenic	As	5.7
Arsenopyrite	$FeAsS$	6.0
Asbestos	See Sec 3	...
Asphaltum	Liquid and solid hydrocarbon	1–1.8
Atacamite	$Cu_2(OH)_3Cl$	3.75
Augite	Pyroxene	...
Aurichalcite	$2(Zn, Cu)CO_3\cdot 3(Zn, Cu)(OH)_2$	3.6
Azurite	$2CuCO_3\cdot Cu(OH)_2$	3.8
Baddeleyite	ZrO_2	5.8
Barite	$BaSO_4$	4.5
Bauxite	$Al_2O_3\cdot 2H_2O$	2.55
Bentonite	SiO_2, Al_2O_3, Fe_2O_3, CaO, MgO	2.13
Beryl	$Be_3Al_2(SiO_3)_6$	2.7
Beryllonite	$NaBePO_4$	2.84
Biotite	$(H, K)_2(Mg, Fe)_2Al_2(SiO_4)_3$ [b]	2.9
Bismite	Bi_2O_3	4.4
Bismuth	Bi	9.8
Bismuthinite	Bi_2S_3	6.45
Bismutite	$(BiO)_2\cdot CO_3\cdot H_2O$	7.3
Blende	Sphalerite	...
Boracite	$Mg_7Cl_2B_{16}O_{30}$	3
Borax	$Na_2B_4O_7\cdot 10H_2O$	1.7
Bornite	$Cu_2S\cdot CuS\cdot FeS$	4.15
Bort	C	3.5
Bournonite	$PbCuSbS_3$	5.8
Braunite	$3Mn_2O_3\cdot MnSiO_3$	4.8
Brochantite	$CuSO_4\cdot 3Cu(OH)_2$	3.9
Bromyrite	$AgBr$	5.9
Brookite	TiO_2	3.9
Brucite	$Mg(OH)_2$	2.4
Calamine	$(ZnOH)_2\cdot SiO_3$	3.45
Calaverite	$(Au\cdot Ag)Te_2$	9.0
Calcite	$CaCO_3$	2.71
Caliche	Soda niter	...
Carbonado	C	3.5
Carnallite	$KCl\cdot MgCl_2 + 6H_2O$	1.6
Carnotite	$K_2O\cdot 2U_2O_3\cdot V_2O_5\cdot 3H_2O$	...
Cassiterite	SnO_2	7.0
Celestite	$SrSO_4$	3.95
Cerargyrite	$AgCl$	5.55

Table 46. Composition and specific gravity of minerals—*Continued*

Mineral	Composition	Sp. gr.*a*
Cerussite	$PbCO_3$	6.5
Cervantite	Sb_2O_4	4.5
Chabazite	$(Ca, Na_2)Al_2Si_4O_{12} + 6H_2O$	2.1
Chalcanthite	$CuSO_4 \cdot 5H_2O$	2.2
Chalcedony	SiO_2	2.62
Chalcocite	Cu_2S	5.65
Chalcopyrite	$CuFeS_2$	4.2
Chalk	$CaCO_3$	....
Chert	SiO_2	2.6
Chloanthite	$NiAs_2$	6.5
Chlorite	$H_4(Mg, Fe)_3Si_2O_9 + H_4(Mg, Fe)Al_2SiO_9$	2.9
Chromite	$FeCr_2O_4$	4.45
Chrysoberyl	$BeAl_2O_4$	3.7
Chrysocolla	$CuSiO_3 + 2H_2O$	2.1
Chrysolite	$(Mg \cdot Fe)_2SiO_4$	3.3
Chrysotile	$H_4Mg_3Si_2O_9$	2.22
Cinnabar	HgS	8.1
Clay	Kaolinite	....
Cleiophane	Sphalerite	....
Clinochlore	$4H_2O \cdot 5MgO \cdot Al_2O_3 \cdot 3SiO_2$	2.7
Coal	(C + H + O + N) varies	1–1.8
Cobaltite	CoAsS	6.15
Colemanite	$Ca_2B_6O_{11} \cdot 5H_2O$	2.4
Columbite	$(Fe, Mn)(Nb, Ta)_2O_6$ *h*	6.3
Copper	Cu	8.8
Coquimbite	$Fe_2(SO_4)_3 + 9H_2O$	2.1
Corundum	Al_2O_3	4.0
Covellite	CuS	4.6
Crocidolite	$NaFe(SiO_3)_2 \cdot FeSiO_3$	3.25
Crocoite	$PbCrO_4$	6.0
Cryolite	Na_3AlF_6	3.0
Cuprite	Cu_2O	6.0
Cyanite	$Al_2O_3 \cdot SiO_2$	3.6
Datolite	$Ca(BOH)SiO_4$	2.95
Descloizite	$4RO \cdot V_2O_5 \cdot H_2O$ *d*	6.0
Diamond	C	3.5
Diaspore	$Al_2O_3 \cdot H_2O$	3.4
Diatomite	SiO_2	....
Diopside	Pyroxene	....
Dolomite	$(Ca, MgCO_3)_2$	2.85
Domeykite	Cu_3As	7.5
Dufrenite	$FePO_4 \cdot Fe(OH)_3$	3.3
Dyscrasite	Ag_3Sb	9.65
Emerald	Beryl	....
Emery	Corundum	....
Enargite	Cu_3AsS_4	4.45
Enstatite	$MgSiO_3$	3.2
Epidote	$Ca_2(AlOH)Al_2(SiO_4)_3$	3.4
Epsomite	$MgSO_4 + 7H_2O$	1.7
Erythrite	$Co_3As_2O_8 \cdot 8H_2O$	2.95
Feldspar	See Sec. 3	....
Ferberite	Wolframite	....
Fergusonite	$R^{III}(Nb, Ta)O_4$ *f*	5.8
Flint	SiO_2	....
Fluorite	CaF_2	3.1
Franklinite	$(Zn, Fe, Mn)O \cdot (Fe, Mn)_2O_3$	5.15
French chalk	Talc	....
Fuller's earth	Smectite and kaolinite	2.0
Galena	PbS	7.5
Garnet	See Sec. 3	....
Garnierite	$H_2(Ni \cdot Mg)SiO_4 + H_2O$	2.5
Gibbsite	$Al(OH)_3$	2.35
Gilsonite	Asphalt	1.07
Glauberite	$Na_2SO_4 \cdot CaSO_4$	2.8
Glauconite	$(K_2O)_x(Fe_2O_3)_y(H_2O)_z(SiO_2)_w$ *e*	2.3
Glaucophane	$NaAl(SiO_3)_2 \cdot (Fe, Mg)SiO_3$	3.1
Gold	Au(±Ag, Cu, Fe)	17.5
Göthite	FeO(OH)	4.2
Graphite	C	2.15

Table 46. Composition and specific gravity of minerals—*Continued*

Mineral	Composition	Sp. gr.[a]
Greenockite	CdS	5.0
Grossularite	$Ca_3Al_2(SiO_4)_3$	3.6
Gypsum	$CaSO_4 + 2H_2O$	2.32
Halite	$NaCl$	2.5
Halloysite	$H_4Al_2O_3 \cdot 2SiO_2 + H_2O$ [b]	2.1
Hambergite	$Be_2(OH)BO_3$	2.35
Haüynite	$Na_2Ca(Na_2SO_4 \cdot Al)Al_2Si_3O_{12}$	2.45
Helvite	$(Mn, Fe)_2(Mn_2S)Be_3(SiO_4)_3$	3.25
Hematite	Fe_2O_3	5.1
Hercynite	$FeAl_2O_4$	3.9
Herderite	$(CaF)BePO_4$	3.0
Hessite	Ag_2Te	8.6
Heulandite	$H_4CaAl_2Si_6O_{18} + 3H_2O$	2.2
Hornblende	$x(Ca(Mg, Fe)_3(SiO_3)_4) + y((Al, Fe)(F, OH)SiO_3)$	±3.2
Hübnerite	$MnWO_4$	6.8
Hydromagnesite	$3MgCO_3 \cdot Mg(OH)_2 + 3H_2O$	2.15
Hydrozincite	$ZnCO_3 \cdot 2Zn(OH)_2$	3.7
Hypersthene	$(Fe, Mg)SiO_3$	3.45
Ilmenite	$FeTiO_3$	4.75
Infusorial earth	SiO_2	....
Iodobromite	$2AgCl \cdot 2AgBr \cdot AgI$	5.7
Iodyrite	AgI	5.6–5.7
Iridium	$Ir(\pm Pt, Os, Rh, Ru, etc.)$	22.7
Iridosmine	$Ir, Os(\pm Rh, Pt, Ru, etc.)$	20
Iron	$Fe(+Ni, Co, Cu, C, SiO_2)$	7.5
Jadeite	$NaAl(SiO_3)_2$	3.33
Jamesonite	$2PbS \cdot Sb_2S_3$	5.8
Jarosite	$K_2O \cdot 3Fe_2O_3 \cdot 4SO_3 \cdot 6H_2O$ [l]	....
Jasper	Quartz	....
Kainite	$MgSO_4 \cdot KCl + 3H_2O$	2.1
Kalinite	$K_2SO_4 \cdot Al_2(SO_4)_3 + 24H_2O$	1.75
Kaolinite	$H_4Al_2Si_2O_9$	2.6
Kermesite	Sb_2S_2O	4.5
Kyanite	Cyanite	....
Lanthanite	$La_2(CO_3)_3$	2.6
Lapis-lazuli	Lazurite	....
Laumontite	$H_4CaAl_2Si_4O_{14} + 2H_2O$	2.3
Lazulite	$2AlPO_4 \cdot (Fe, Mg)(OH)_2$	3.0
Lazurite	$Na_4(NaS_3 \cdot Al)Al_2Si_3O_{12}$	2.4
Lepidolite	$KLi[Al(OH, F)_2]Al(SiO_3)_3$	2.85
Leucite	$KAl(SiO_3)_2$	2.5
Libethenite	$Cu_3P_2O_8 \cdot Cu(OH)_2$	3.7
Limonite	$2Fe_2O_3 \cdot 3H_2O$	3.8
Linarite	$(Pb, Cu)SO_4 \cdot (Pb, Cu)(OH)_2$	5.4
Linnaeite	$Co_3S_4(\pm Fe, Cu)$	4.9
Livingstonite	$HgS \cdot 2Sb_2S_3$	4.8
Löllingite	$FeAs_2$	7.2
Magnesite	$MgCO_3$	3.05
Magnetite	Fe_3O_4	5.17
Malachite	$CuCO_3 \cdot Cu(OH)_2$	4.0
Maltha	Asphalt	....
Manganite	$Mn_2O_3 \cdot H_2O$	4.3
Marcasite	FeS_2	4.9
Marmatite	$xFeS \cdot yZnS$	3.9
Martite	Fe_2O_3	4.9
Meerschaum	Sepiolite	....
Melaconite	CuO	±6.0
Meliphanite	$NaCa_2Be_2FSi_3O_{10}$	3.0
Mica	See Sec. 3	....
Microcline	$KAlSi_3O_8$	2.55
Microlite	$Ca_2Ta_2O_7$	5.5
Millerite	NiS	5.5
Mimetite	$(PbCl)Pb_4As_3O_{12}$	7.1
Mispickel	Arsenopyrite	....
Molybdenite	MoS_2	4.8
Molybdite	MoO_3	4.5
Monazite	$(Ce, La)PO_4$	5.1
Montmorillonite	$H_2Al_2Si_4O_{12} + nH_2O$	....
Mottramite	$(Pb, Cu)_3V_2O_8 \cdot 2(Pb, Cu)(OH)_2$	5.9

Table 46. Composition and specific gravity of minerals—*Continued*

Mineral	Composition	Sp. gr.*a*
Muscovite	$H_2KAl_3(SiO_4)_3$	2.9
Natrolite	$Na_2Al_2Si_3O_{10} + 2H_2O$	2.2
Natron	$Na_2CO_3 + 10H_2O$	1.45
Nephelite	$NaAlSiO_4$	2.6
Niccolite	NiAs	7.5
Niter	KNO_3	2.1
Ocher	Powdery $Fe_2(OH)_6 \cdot Fe_2O_3$	±4
Octahedrite	TiO_2	3.9
Oligoclase	Feldspar; see Sec. 3	
Olivine	$(Mg, Fe)_2SiO_4$	3.3
Opal	SiO_2	2.1
Orpiment	As_2S_3	3.45
Orthoclase	$KAlSi_3O_8$	2.5
Osmiridium	Iridosmine	
Ozocerite	Hydrocarbon	0.9
Palladium	Pd(±Pt, Ir)	11.5
Pentlandite	(Fe, Ni)S	4.8
Perovskite	$CaO \cdot TiO_2$	3.95–4.1
Petzite	$(Ag, Au)_2Te$	8.9
Phenacite	Be_2SiO_4	3.0
Phlogopite	$(H, K, MgF)Mg_3Al(SiO_4)_3$	2.8
Phosphorite	Apatite	
Picotite	$(Mg, Fe)O \cdot (Al, Cr)_2O_3$	4.1
Plagioclase	Albite; anorthite	
Platinum	Pt(±Fe, Ir, Os, etc.)	17
Pleonaste	Spinel	
Polybasite	$(Ag, Cu)_{16}Sb_2S_{11}$	6.1
Polycrase	$R^{III}(NbO_3)_3 \cdot 2R^{III}(TiO_3)_3 \cdot 3H_2O$ *f*	5.0
Polyhalite	$2CaSO_4 \cdot MgSO_4 \cdot K_2SO_4 + 2H_2O$	2.78
Prehnite	$H_2Ca_2Al_2Si_3O_{12}$	2.9
Proustite	Ag_3AsS_3	5.6
Psilomelane	H_4MnO_5 *b*	4.2
Pyrargyrite	Ag_3SbS_3	5.8

Willemite	Zn_2SiO_4	4.1
Witherite	$BaCO_3$	4.3
Wöhlerite	$12(CaNa_2)(SiZr)O_3 \cdot (CaNa_2)Nb_2O_6$ *m*	3.42
Wolframite	$(Fe, Mn)WO_4$	7.4
Wollastonite	$CaSiO_3$	2.85
Wulfenite	$PbMoO_4$	6.9
Wurtzite	ZnS	3.98
Yttrialite	$R_2O_3 \cdot 2SiO_2$ *k*	4.6
Zincite	ZnO	5.6
Zircon	$ZrSiO_4$	4.7
Zoisite	$HCa_2Al_3Si_3O_{13}$	3.3

a Average.
b Approximate.
c R = Fe, Mg and the alkalies.
d R = Pb, Zn chiefly, usually about 1 : 1.
e Proportions highly variable.
f R^{III} = Yt, Er, Ce, U.
g R^{II} = Fe, $CaUO_3$; R^{III} = Ce, Yt.
h Nb predominating.
i Ta predominating.
j R = Fe, Mn, Ca, Mg.
k Th- and Yt-group metals chiefly.
l Pb and Ag frequently either a part of the mineral or in mineral forms closely associated.
m Ca : Na_2 = nearly 4 : 1.
n R = Ce, Ca, Ti, Th principally.

Table 47. Abbreviations used in text

AC	American Cyanamid Co.
A-C	Allis-Chalmers Mfg. Co.
a-c.	Alternating current.
ACI	Annealed cast iron.
addl.	Additional.
amp.	Ampere.
approx.	Approximate.
Art.	Article.
asst.	Assistant.
A.T.	Assay ton.
atm.	Atmosphere.
auto.	Automatic.
aver.	Average.
bbl.	Barrel.
bd. ft.	Board-feet.
Bé.	Baumé.
b. hp.	Boiler horsepower.
b. hp.	Brake horsepower.
B.M.	Board measure.
b.p.	Boiling point.
B.P.L.	Bone phosphate of lime.
B.t.u.	British thermal units.
C.	Centigrade.
°C.	Degrees Centigrade.
cal.	Calorie.
capac.	Capacity.
CAS	Cast alloy steel.
CC	Closed circuit.
cc.	Cubic centimeter(s).
CCI	Chilled cast iron.
CF	Composite feed.
c.f.	Cubic foot (feet).
c.f.m.	cubic feet per minute.
c.g.	Center of gravity.
c.g.s.	Centimeter-gram-second.
CI	Cast iron.
c.i.f.	Cost, insurance, freight.
circ.	Circulating.
CO	Classifier overflow.
col.	Column.
conc.	Concentrate.
concn.	Concentration.
conv.	Conveyor.
corp.	Corporation.
cp.	Centipoise.
c-p.	Candle-power.
C.P.	Chemically pure.
Cr	Chrome steel.
Cr-Mo	Chrome-molybdenum steel.
Cr-Ni	Chrome-nickel steel.
CS	Cast steel.
CSS	Cast semi-steel.
c. to c.	Center to center.
cts.	Cents.
cu. ft.	Cubic foot (feet).
cum.	Cumulative.
cyd.	Cubic yard.
cyl.	Cylinder.
da.	Day.
d-c.	Direct current.
DC	Dorr classifier.
dcm.	Decimeter.
deg. F.	Degree Fahrenheit.
diag.	Diagonal.
diam.	Diameter.
dir.	Direct.
distrib.	Distribution.

do.	Ditto.
dr.	Dram.
dwt.	Pennyweight.
ea.	Each.
effic.	Efficiency.
Eq.	Equation.
F.	Fahrenheit.
f.a.s.	Free alongside (ship).
fgt.	Freight.
Fig.	Figure.
flot. / flotn.	Flotation.
f.o.b.	Free on board.
f.p.m.	Feet per minute.
f.p.s.	Feet per second.
f.p.s.p.s.	Feet per second per second.
FS	Forged steel.
ft.	Feet.
gal.	Gallons.
gen'l	General.
gm.	Gram.
g.p.h.	Gallons per hour.
g.p.cyd.	Gallons per cubic yard.
g.p.m.	Gallons per minute.
g.p.t.	Gallons per ton.
gr.	Grain.
griz.	Grizzly.
gyr.	Gyratory.
H	Hardness
HCS	High-carbon steel.
Hf	Hard-faced; hard-surfaced.
hgt.	Height.
hp.	Horsepower.
hp-day	Horsepower-day.
hp-hr.	Horsepower-hour.
hp-mo.	Horsepower-month.
hr.	Hour.
I&A	Iron and aluminum.
I.B.P.	Initial boiling point.
I.D.	Inside diameter.
in.	Inch.
incl.	Including.
in. per ft. / i.p.f.	Inches per foot.
insol.	Insoluble.
int.	Intermediate.
kg.	Kilogram.
kg-cal.	Kilogram-calorie.
km.	kilometer.
kva. / k.v.a. / kv-a.	Kilovolt-ampere(s).
kw.	Kilowatt.
kw-hr.	Kilowatt hour.
lb.	Pound.
li.	Liter.
lin.	Linear.
M	Mark.
m.	Mesh.
ma.	Milliampere.
man-hr.	Man hour.
mat'l	Material.
max.	Maximum.

Table 47. Abbreviations used in text—*Continued*

MBI	Metals Beneficiation, Inc.
M.B.M.	Thousand board feet.
Md	Manganoid.
mg.	Milligram.
mgr.	Manager.
mi.	Mile.
min.	Minute, minimum.
misc.	Miscellaneous.
mm.	Millimeter(s).
mo.	Month.
mog	Mesh-of-grind.
M.P.	Melting point.
m.p.r.	Minutes per revolution.
M-S	Minerals separation.
MW	Multiple wave.
N.A.	Numerical aperture.
negl.	Negligible.
no.	Number.
OC	Open circuit.
O.D.	Outside diameter.
orig.	Original.
oz.	Ounce.
pf.	Power factor.
Pl.	Plate.
p.p.m.	Parts per million.
prim.	Primary.
prod.	Product.
p.s.i.	Pounds per square inch.
pulv.	Pulverized.
rd.	Round.
recip.	Reciprocal.
recl.	Reclaimed.
regr.	Regrind.
retreat.	Retreatment.
rev.	Revolutions.
Rm.	Reichsmark.
r.o.m.	Run-of-mine.
r.p.h.	Revolutions per hour.
r.p.m.	Revolutions per minute.
r.p.s.	Revolutions per second.
R.R.	Railroad.
scav.	Scavenger.
scr.	Screen.
Sec.	Section.
sec.	Second.
sp. gr. spec. grav.	Specific gravity.
sp. ht.	Specific heat.
spig.	Spigot.
s.p.m.	Strokes per minute.
sq. ft.	Square foot (feet).
sq. in.	Square inch(es).
sq. mi.	Square mile(s).
sq. mm.	Square millimeter(s).
std.	Standard.
stl.	Steel.
sup't	Superintendent.
susp.	Suspended.
symbols	
>	Retained on; greater than; larger than.
<	Passing; less than; smaller than.
~	Ranging between.
@	At; of the size or description following.
syn.	Synthetic.
temp.	Temperature.
TFS	Tempered forged steel.
theor.	Theoretical.
t.p.d.	Tons per day.
t.p.h.	Tons per hour.
t.p.m.	Tons per minute.
tr.	Trace.
TS	Tool steel.
v.	Volt.
veloc.	Velocity.
vert.	Vertical.
vib.	Vibration(s).
vol.	Volume.
v.p.m.	Vibrations per minute.
WB	Wedge bar.
wgt.	Weight.
WhI	White iron.
wk.	Week.
wt.	Weight.
yd.	Yard.
yr.	Year.

Table 48. Abbreviations used in literature citations

References to articles in periodicals are written in the order: volume number, name or abbreviation for name of periodical, page number; thus *100 J 110* is to be read, Engineering and Mining Journal, vol. 100, page 110. References to books are by name, abbreviation, or by author's name in italics, the distinctions being based largely on frequency of reference and danger of confusion. An alphabetical list of the abbreviations of book and periodical names used follows.

A	American Institute of Mining & Metallurgical Engineers.
Aa	Australasian Institute of Mining & Metallurgy (new series).
AC	American Cyanamid Co.
ABMS	American Bureau of Metal Statistics, N. Y.
ACerS	Journal of the American Ceramic Society.
ACS	Journal of the American Chemical Society.
Adam	Physics and chemistry of surfaces, Neil K. Adam, Oxford, Clarendon Press, 1930.
AES	American Electrochemical Society.
AIChE	American Institute of Chemical Engineers.
AIM	American Institute of Metals.
AIME	American Institute of Mining & Metallurgical Engineers.
AJS	American Journal of Science.
Alden	Design of industrial exhaust systems, John L. Alden, Industrial Press, N. Y., 1939.
Am. I. & S. Inst.	American Iron & Steel Institute.
AP	Journal of Applied Physics.
ASA	American Standards Association.
ASCE	Proceedings of the American Society of Civil Engineers.
ASM	Transactions American Society of Metals.
ASME	Transactions American Society of Mechanical Engineers.
ASTM	American Society for Testing Materials.
AZI	American Zinc Institute Journal.
Ber	Berichte.
Bowie	A practical treatise on hydraulic mining in California, A. J. Bowie, Jr., D. Van Nostrand Co., 1905.
Bray	Non-ferrous production metallurgy, J. L. Bray, John Wiley & Sons, 1941.
BSTJ	Bell System Technical Journal.
Bul	Bulletin.
C	Combustion.
CA	Coal Age.
CAL	Chemical Age, London.
CE	Colliery Engineering.
CEG	Conclusions from experiments in grinding, W. H. Coghill and F. D. de Vaney, Bul, Sept. 1938, Technical Series, Missouri School of Mines and Metallurgy.
CEMR	Chemical Engineering & Mining Review.
CENY	Civil Engineering, N. Y.
CerS	Ceramic Society, London.
CG	Colliery Guardian.
ChA	Chemical Abstracts.
CI	Chemistry & Industry.
CIE	Cornish Institute of Engineers.
CIMM	Transactions Canadian Institute of Mining & Metallurgy.
CLM	Cement & Lime Manufacture.
CM	Chemical Markets.
CMB	Canadian Department of Mines & Resources, Mines & Geology Branch, Bureau of Mines Report.
CME	Chemical & Metallurgical Engineering.
CMI	Transactions Canadian Mining Institute.
CMJ	Canadian Mining Journal.
Coll. Eng.	Colliery Engineering.
CSMM	Colorado School of Mines Magazine.
CSMQ	Colorado School of Mines Quarterly.
Ct	Concrete.
CU	Columbia University.
CvE	Civil Engineering.
D	Discussion.
Dana	System of mineralogy, J. N. Dana, John Wiley & Sons, 1903; Textbook of mineralogy, Dana and Ford (W. E.), John Wiley & Sons, 1922.
DECO	Denver Equipment Co.
Dorr	Cyanidation and concentration of gold and silver ores, J. V. N. Dorr, McGraw-Hill Book Co., 1936.
E	Engineering.
Ed. 1	Edition 1, Handbook of Ore Dressing, Arthur F. Taggart, John Wiley & Sons, 1927.
EE	Electrical Engineering.
EG	Economic Geology.
EL	Engineering, London.
EN	Engineering News; Engineering News-Record.
Eng.	Engineering, N. Y.
ER	Electrical Review.
EW	Electrical World.
F	Flotation, A. M. Gaudin, McGraw-Hill Book Co., 1932.
FMQ	Foreign Minerals Quarterly.
G or *Gl*	Glückauf.
GSA	Geological Survey of Alabama.
GSSAf	Geological Survey of South Africa.
Hahn	Applied radio-chemistry, Otto Hahn, Cornell University Press, 1936.
Hammett	Solutions of electrolytes, L. P. Hammett, McGraw-Hill Book Co., 1936.

Table 48. Abbreviations used in literature citations—*Continued*

Hayward	An outline of metallurgical practice, C. R. Hayward, D. Van Nostrand Co., 1940.
Hetzel	Belt conveyors and belt elevators, F. V. Hetzel, John Wiley & Sons, 1922.
Hoover	Concentrating ores by flotation, T. J. Hoover, Mining Magazine, London, 1916.
HPAC	Heating, Plumbing, and Air-conditioning.
HS	Hollinger Staff.
HV	Heating and Ventilation
IBMG	Idaho Bureau of Mines and Geology.
IC	Information Circular, U. S. Bureau of Mines.
ICE	Institution of Chemical Engineers.
ICh	Industrial Chemist.
IEC	Industrial & Engineering Chemistry.
IECA	Industrial & Engineering Chemistry, Analytical Edition.
IME	Transactions Institute of Mining Engineers.
IMeE	Institute of Mechanical Engineers.
IMI	Proceedings Illinois Mining Institute.
IMM	Institution of Mining & Metallurgy, Transactions.
IMR	Industrial Minerals and Rocks, AIME.
J	Engineering & Mining Journal.
Janin	Bulletin 127, United States Bureau of Mines.
JCM	Journal of the Chemical, Mining & Metallurgical Society of South Africa.
JFI	Journal of the Franklin Institute.
JG	Journal of Geology.
JIF	Journal of the Institute of Fuel.
Johannsen	Manual of petrographic methods, Albert Johannsen, McGraw-Hill Book Co., 1918.
JPC	Journal of Physical Chemistry.
JPCR	Scientific Papers, Institute of Physical & Chemical Research, Tokyo.
JSAIE	Journal of the South African Institute of Engineers.
Julian, Smart, and Allen	Cyaniding gold and silver ores, H. Forbes Julian and Edgar Smart; 3rd ed., J. B. Lippincott Co.
KB	Kolloid-Beihefte.
KC	Kolloid Chemie
Ketchum	The design of walls, bins, and grain elevators, Milo S. Ketchum, McGraw-Hill Book Co., 1919.
Kidder	The architects' and builders' handbook, F. E. Kidder and Harry Parker, John Wiley & Sons, 1935.
KZ	Kolloid Zeitschrift.
Ladoo	Non-metallic minerals, Raymond B. Ladoo, McGraw-Hill Book Co., 1925.
Liddell	Handbook of nonferrous metallurgy, McGraw-Hill Book Co., 1926.
Louis	The dressing of minerals, Henry Louis, Arnold, London, 1909.
LSMI	Proceedings Lake Superior Mining Institute.
LSS	Lake Shore Staff.
LVS	Landwirtschaftlichen Versuchsstationen.
Marks	Mechanical engineers' handbook, L. S. Marks, McGraw-Hill Book Co., 1916.
MCJ	Mining Congress Journal.
MCR	Mining & Contracting Review.
ME	Metall und Erz.
Mellor	A comprehensive treatise on inorganic and theoretical chemistry, J. W. Mellor, Longmans, Green & Co.
Merriman	Mechanics of materials, Mansfield Merriman, John Wiley & Sons, 1906.
MEW	Mining & Engineering World.
MH	Mines Handbook, W. H. Weed, The Mines Handbook Co., Annual.
MI	Mineral Industry.
Miller	Crushers for stone and ore, W. T. W. Miller, Mining Publications, Ltd., London, 1935.
MIMM	Mexican Institution of Mining & Metallurgy.
MJ	Mining Journal, London.
MJA	Mining Journal of Arizona.
MM	Mining Magazine.
M&M	Mines & Minerals.
MMC	Mines Magazine, Colorado School of Mines.
MMt	Mining & Metallurgy.
MoMM	Missouri School of Mining & Metallurgy.
MQE	Mine & Quarry Engineering.
MR	Mineral Resources.
MSM	Minnesota School of Mines.
MT	Mining Technology, AIME.
Murdoch	Microscopical determination of the opaque minerals, Jos. Murdoch, John Wiley & Sons, 1916.
MW	Mining World.
MY	Minerals Yearbook, U. S. Bureau of Mines.
N	Nature.
NACA	National Advisory Committee for Aeronautics.
NS	New Series.
OD	Ore dressing, R. H. Richards, McGraw-Hill Book Co., 1908.
OD Notes	Ore dressing notes, American Cyanamid Co.
P	Mining & Scientific Press.
Paneth	Radio elements as indicators, Fritz Paneth, McGraw-Hill Book Co., 1928.
Pat	Patent.
PC	Private communication.
